Campbell-Walsh-Wein Urology

TWELFTH EDITION

Editor-in-Chief

Alan W. Partin, MD, PhD

The Jakurski Family Director, Urologist-in-Chief, Chairman, Department of Urology
Professor, Departments of Urology, Oncology and Pathology, Johns Hopkins Medical Institutions, Baltimore, Maryland
Editors

Roger R. Dmochowski, MD, MMHC, FACS

Professor, Urologic Surgery, Surgery and Gynecology
Program Director, Female Pelvic Medicine and Reconstructive Surgery
Vice Chair for Faculty Affairs and Professionalism, Section of Surgical Sciences
Associate Surgeon-in-Chief, Vanderbilt University Medical Center, Nashville, Tennessee

Louis R. Kavoussi, MD, MBA

Professor and Chair, Department of Urology, Zucker School of Medicine at Hofstra/Northwell, Hempstead, New York;
Chairman of Urology, The Arthur Smith Institute for Urology, Lake Success, New York

Craig A. Peters, MD

Chief, Pediatric Urology, Children's Health System Texas;
Professor of Urology, University of Texas Southwestern, Medical Center, Dallas, Texas

Volume I

Part I Clinical Decision Making

1 Evaluation of the Urologic Patient

- History
- Physical Examination

Special Populations

Conclusion

References

2 Evaluation of the Urologic Patient

Urinalysis

Chemical Examination of Urine

Summary

References

3 Urinary Tract Imaging

Conventional Radiography

Radiation Management in Uroradiology

Contrast Media

Intravenous Urography

Plain Abdominal Radiography

Retrograde Pyelography

Loopography

Retrograde Urethrography

Static Cystography

Voiding Cystourethrogram

Nuclear Scintigraphy

Computed Tomography

Magnetic Resonance Imaging

Acknowledgments

References

4 Urinary Tract Imaging

Brief History of Ultrasound in Urology

Physical Principles

Modes of Ultrasound

Contrast Agents in Ultrasound

Patient Safety

Clinical Urologic Ultrasound

Practice Accreditation

Suggested Readings

References

5 Urinary Tract Imaging

Principles of Single Photon and PET Imaging

Functional Imaging of the Kidneys

Infection Imaging

Molecular Imaging of Genitourinary Malignancies

- References

6 Assessment of Urologic and Surgical Outcomes

- Establishing a Conceptual Framework for Assessing the Effectiveness of Treatment and Improving Care in Urology
- Long-Term Disease Outcomes That Are Commonly Assessed in Urology
- Commonly Assessed Short-Term Outcomes
- Patient-Reported Outcomes
- Other Outcomes of Interest in Urology
- References

7 Ethics and Informed Consent

- Medical Ethics
- Informed Consent
- References

Part II Basics of Urologic Surgery

8 Principles of Urologic Surgery

- Preoperative Evaluation
- Presurgical Testing
- Preoperative Cardiovascular Evaluation
- Pulmonary Evaluation

Hepatobiliary Evaluation
Special Populations
Preparation for Surgery
Intraoperative Management
Acknowledgments
Suggested Readings
References

9 Principles of Urologic Surgery
Abdominal Incisions
Anterior Approaches to the Kidney and Retroperitoneum
Flank Incisions
Inguinal Incisions
Incisions for Specific Surgeries
Suggested Readings
References

10 Principles of Urologic Surgery
Patient Environment
Blood Products
Drains
Suture Material and Incision Closure

References

11 Lower Urinary Tract Catheterization

History

Anatomic Considerations

Indications for Lower Urinary Tract Drainage

Technique of Urethral Catheterization

Suprapubic Catheterization

Difficult Catheterization

Complications of Lower Urinary Tract Drainage

References

12 Fundamentals of Upper Urinary Tract Drainage

Percutaneous Renal Access and Drainage

Retrograde Renal Access and Drainage

References

13 Principles of Urologic Endoscopy

Introduction

History of Endoscopy

Basic Equipment and Video-Endoscopic Systems

Cystourethroscopy

Upper-Tract Endoscopy

Conclusion

Suggested Readings

References

14 Fundamentals of Laparoscopic and Robotic Urologic Surgery

Preoperative Preparation

Operating Room

Strategic Placement of Operative Team and Equipment

Performing the Procedure

Physiologic Considerations in the Adult

Complications and Troubleshooting in Laparoscopic and Robotic Surgery

Training and Practicing Laparoscopic and Robotic Surgery

Conclusion

Acknowledgment

Suggested Readings

References

15 Basic Energy Modalities in Urologic Surgery

Tissue Dissection and Cauterization

Intracorporeal Lithotripters

- Pneumatic Lithotripsy
- Ultrasonic Lithotripsy
- Holmium:YAG and Erbium:YAG Laser Lithotripsy
- Dual-Modality Lithotripters
- Suggested Readings
- References

16 Evaluation and Management of Hematuria

- Classification and Timing of Hematuria
- Microscopic Hematuria
- Guideline-Based Evaluation of Patients With Microhematuria
- Symptomatic Microscopic Hematuria
- Gross Hematuria
- Hemorrhagic Cystitis
- Hematuria From Prostatic Origin
- Urethral Bleeding
- Hematuria Originating From the Upper Urinary Tract
- Suggested Readings
- References

17 Complications of Urologic Surgery

- Classification of Complications

Physiologic Complications

Positional and Neuromuscular Complications

Urinary Complications

Urine Leaks After Upper Tract Urologic Surgery

Ureteral Injuries

Lower Tract Urinary Complications

Vascular Complications

Bowel Injuries

Conclusion

References

18 Urologic Considerations in Pregnancy

Physiologic Changes During Pregnancy

Physiologic Hydronephrosis of Pregnancy

General Considerations for Imaging of the Pregnant Patient

General Concepts for Surgical Management of the Pregnant Patient

General Concepts of Urologic Medication Administration During Pregnancy

Urolithiasis in Pregnancy

Pregnancy in Women With Congenital Urologic Conditions

Functional and Anatomic Urologic Concerns During Pregnancy

Urologic Malignancy During Pregnancy

Management of Urinary Tract Infections in Pregnancy

Urologic Management of Placental Abnormalities

Acknowledgments

References

19 Intraoperative Consultation

Ethical Considerations

Decision Making

Documentation

Urethral Injury

Bladder Injury

Ureteral Injury

Renal Injury

Placental Cases

References

Part III Pediatric Urology

Section A Development and Prenatal Urology

20 Embryology of the Genitourinary Tract

Development of the External Genitalia

Development of the Female External Genitalia

Development of the Human Prostate

Development of the Human Seminal Vesicle

Development of the Gonads

Müllerian Structures (Female Internal Genitalia)

Development of the Ureter

Kidneys

Acknowledgment

Suggested Readings

References

21 Urologic Aspects of Pediatric Nephrology

Introduction

Renal Function, Fluid, and Electrolyte Homeostasis

Hematuria (Microscopic and Gross)

Proteinuria

Glomerular Disease

Tubulopathies

Cystic Renal Disease

Urolithiasis: Medical Management

Hypertension

Acute Kidney Injury

Chronic Kidney Disease

End-Stage Renal Disease: Dialysis and Renal Transplantation

Summary

Suggested Readings

References

22 Perinatal Urology

Prenatal Imaging

Grading Systems

Prenatal Multidisciplinary Consultations

Urinary Tract Dilation

Postnatal Evaluation and Management

Management Recommendations for Postnatal Urinary Tract Dilation

Key Conditions

Lower Urinary Tract Obstruction (Posterior Urethral Valve, Prune Belly Syndrome, Urethral Stenosis/Atresia)

Kidney Anomalies

Exstrophy (Bladder/Cloacal)

Urogenital Sinus/Congenital Adrenal Hyperplasia

Perinatal Urgencies/Emergencies

References

Section B Basic Principles

23 Urologic Evaluation of the Child

Overview of Pediatric Urology

Imaging

Presentations by Genitourinary Region

Acknowledgments

References

24 Pediatric Urogenital Imaging

Technique

sonography

Magnetic Resonance Imaging

Conventional Radiography

Voiding Cystourethrography/Micturating Cystourethrogram

Computed Tomography

DMSA Renal Cortical Scintigraphy

Diuretic Renal Scintigraphy

Radionuclide Cystography

Radionuclide Testicular Scanning

Suggested Readings

References

25 Infection and Inflammation of the Pediatric Genitourinary Tract

Evaluation and Management of a Child With a Fever

Classification of Pediatric Urinary Tract Infections

Diagnosis of Pediatric Urinary Tract Infection

Management of Pediatric Urinary Tract Infection

Management After Urinary Tract Infection

Sequelae of Pediatric Urinary Tract Infections

Uncommon Pediatric Urinary Tract Infections

Suggested Readings

References

26 Core Principles of Perioperative Management in Children

Pediatric Anesthesia

Preoperative Assessment and Preparation for Surgery

Comorbidities: Perioperative Planning and Postoperative Considerations

ERAS Protocols

Laparoscopic Procedures

Opioid Use in Children

- References

27 Principles of Laparoscopic and Robotic Surgery in Children

- Advantages and Disadvantages of Minimally Invasive Surgery
- Physiology of the Pneumoperitoneum
- Patient Selection for Mimimally Invasive Surgery
- Access
- Approach
- Equipment and Instrumentation
- Complications of Minimally Invasive Surgery
- Simulation Training and Evaluation
- Conclusion
- Suggested Readings
- References

Section C Lower Urinary Tract Conditions

---

28 Clinical and Urodynamic Evaluation of Lower Urinary Tract Dysfunction in Children

- Clinical Evaluation
- Laboratory Testing
- Urodynamic Evaluation

Evaluation Strategies for Specific Clinical Entities

Acknowledgments

Suggested Readings

References

29 Management Strategies for Vesicoureteral Reflux

Historical Perspective

Demographics

Inheritance and Genetics

Embryology of the Ureterovesical Junction

Functional Anatomy of the Antireflux Mechanism

Causes of Vesicoureteral Reflux

Urinary Tract Infection and Reflux

Grading of Reflux

Cortical Defects

Diagnosis and Evaluation of Vesicoureteral Reflux

Assessment of the Lower Urinary Tract

Assessment of the Upper Urinary Tract

Controversies in Usage of Invasive Investigations

Associated Anomalies and Conditions

Natural History and Management

References

30 Bladder Anomalies in Children

Congenital Bladder Anomalies

Acquired Bladder Anomalies in Children

Acknowledgments

References

31 Exstrophy-Epispadias Complex

Historical Aspects

Incidence and Inheritance

Embryology

Classic Bladder Exstrophy

Surgical Reconstruction of Bladder Exstrophy

Modern Initial Repair of Bladder Exstrophy: Outcomes and Results

Other Modern Exstrophy Repairs: Continence Outcomes

Exstrophy Reconstruction Failures and Complications

Transitional Exstrophy Patient: Adolescent and Adult Concerns

Continence

Male Concerns

Female Concerns

Quality of Life

- Long-Term Adjustment Issues
- Epispadias
- Cloacal Exstrophy
- Surgical Reconstruction of Cloacal Exstrophy
- Long-Term Issues in Cloacal Exstrophy
- Summary
- Dedication
- Acknowledgment
- Suggested Readings
- References

32 Prune-Belly Syndrome

- Genetics
- Embryology
- Clinical Features of Prune-Belly Syndrome
- Presentation
- Evaluation and Management
- Long-Term Outlook
- Suggested Readings
- References

33 Posterior Urethral Valves

Background

Epidemiology

Pathophysiology of Posterior Urethral Valves

Diagnosis

Clinical Presentation and Initial Management

Surgical Intervention

Management of Vesicoureteral Reflux

Bladder Dysfunction and Valve Bladder Syndrome

Prognostic Indicators for Renal Function

Transplantation in Valve Patients

Quality of Life With Posterior Urethral Valves

Anterior Urethral Valves

Urethral Atresia

Urethral Duplication

Urethrorrhagia

Urinary Fistula in Boys With Anorectal Malformation

Suggested Readings

References

34 Neuromuscular Dysfunction of the Lower Urinary Tract in Children

Neural Tube Defects

Management of Neuromuscular Dysfunction of the Lower Urinary Tract

Management of Vesicoureteral Reflux in Neuropathic Dysfunction of the Lower Urinary Tract

Lipomeningocele and Other Spinal Dysraphisms

Sacral Agenesis

Conditions of the Pelvis

Central Nervous System Insults

Conditions of the Brain (Tumors/Infarcts/Encephalopathies)

Conditions of the Spinal Cord

Suggested Readings

References

35 Functional Disorders of the Lower Urinary Tract in Children

Clinical Significance

Epidemiology

Self-Esteem and Quality-of-Life Issues

Comorbidities

Terminology

Daytime Urinary Incontinence and Bladder Dysfunction

Enuresis

Suggested Readings

References

36 Management of Defecation Disorders

Epidemiology and Classification of Disorders of Defecation

Management

Suggested Readings

References

37 Lower Urinary Tract Reconstruction in Children

“Functional” Urinary Tract

Patient Evaluation

Patient Preparation

Antireflux

Bladder Neck Reconstruction

Bladder Reconstruction

Augmentation Cystoplasty

Continent Urinary Diversion

Summary

Suggested Readings

References

Section D Upper Urinary Tract Conditions

38 Anomalies of the Upper Urinary Tract
  - Anomalies of Renal Number
  - Anomalies of Renal Ascent
  - Anomalies of Renal Form and Fusion
  - Anomalies of Renal Rotation
  - Anomalies of Renal Vasculature
  - Renal Artery Aneurysm
  - Anomalies of the Renal Collecting System
  - Acknowledgments
  - References

39 Renal Dysgenesis and Cystic Disease of the Kidney
  - Overview of Genetics
  - Renal Agenesis and Dysplasia
  - Hypoplasia and Hypodysplasia
  - Cystic Diseases of the Kidney
  - Autosomal Recessive (Infantile) Polycystic Kidney Disease
  - Autosomal Dominant (Adult) Polycystic Kidney Disease
  - Juvenile Nephronophthisis and Medullary Cystic Disease Complex

Other Inheritable Renal Cystic Diseases (Congenital Nephrosis)

Familial Hypoplastic Glomerulocystic Kidney Disease (Cortical Microcystic Disease)

Multiple Malformation Syndromes With Renal Cysts

Multicystic Dysplastic Kidney

Benign Multilocular Cyst (Cystic Nephroma)

Simple Cysts

Medullary Sponge Kidney

Sporadic Glomerulocystic Kidney Disease

Acquired Renal Cystic Disease

Calyceal Diverticulum (Pyelogenic Cyst)

Parapelvic and Renal Sinus Cysts

Acknowledgment

Suggested Readings

References

40 Pathophysiology of Urinary Tract Obstruction

Prevalence

Clinical Presentation of Obstruction

Progressive Renal Dysfunction

Definition of Obstruction

- Diagnosis and Imaging
- Pathological Changes of Obstruction
- Tubulointerstitial Fibrosis
- Hemodyamic Changes With Obstruction
- Effects of Obstruction on Tubular Function
- Egress of Urine From the Obstructed Kidney
- Clinical Impact of Renal Obstruction
- Treatment of Renal Obstruction
- Suggested Readings
- References

41 Ectopic Ureter, Ureterocele, and Ureteral Anomalies

- Classification and Anatomic Description
- Clinical Presentation
- Evaluation
- Clinical Management
- Other Ureteral Anomalies
- Suggested Readings
- References

42 Surgery of the Ureter in Children

- Ureteropelvic Junction Obstruction

Vesicoureteric Reflux

Endoscopic Treatment of Vesicoureteral Reflux

Megaureter

Suggested Readings

References

43 Management of Pediatric Kidney Stone Disease

Extrarenal Manifestations

Management of Children and Adolescents With Kidney and Ureteral Stones

Shock Wave Lithotripsy

Percutaneous Nephrolithotomy

Laparoscopic and Robotic-Assisted Pyelolithotomy

References

Section E Genitalia

---

44 Management of Abnormalities of the External Genitalia in Boys

Normal Male External Genitalia

Penile Anomalies

Scrotal Anomalies

Vascular Lesions of the Genitalia

Hernia and Hydroceles

Acute Scrotum

Varicocele

Epididymal and Vasal Anomalies

Suggested Readings

References

45 Hypospadias

Embryology

Diagnosis of Hypospadias

Etiology of Hypospadias

Surgical Assessment

Advancement Procedures

Tubularization Techniques

Hypospadias Outcomes

Future

Suggested Readings

References

46 Etiology, Diagnosis, and Management of the Undescended Testis

Introduction

Definitions

- Etiology
- Diagnosis
- General Guidelines for Management
- Medical Management
- Surgical Management
- Prognosis
- Suggested Readings
- References

47 Management of Abnormalities of the Genitalia in Girls

- Female Genital Embryology
- Evaluation and Classification of Female Genital Anomalies
- Congenital Disorders of Female External Genitalia
- Acquired Disorders of the Female External Genitalia
- Suggested Readings
- References

48 Disorders of Sexual Development

- Normal Sexual Development
- Abnormal Sexual Development
- Evaluation and Management of the Newborn With Ambiguous Genitalia

Suggested Readings

References

Section F Reconstruction and Trauma

49 Surgical Management of Differences of Sexual Differentiation and Cloacal and Anorectal Malformations

Classification of Urogenital Sinus and Cloacal Anomalies

Surgical Reconstruction of Disorders of Sex Development and Urogenital Sinus

Surgical Reconstruction for Cloacal Malformations

Summary

Suggested Readings

References

50 Adolescent and Transitional Urology

Definitions

Patient Population

Setting Up a Service

Barriers to Transition

Clinical Delivery

Patient/Parent Preparation for Transition

Clinical Practice: Major Diagnoses

Male

Females Born With Exstrophy

Spina Bifida: the Neuropathic Bladder

Posterior Urethral Valves

Summary

Suggested Readings

References

51 Urologic Considerations in Pediatric Renal Transplantation

Pretransplant Assessment

Pretransplant Preparation

Transplantation

Complications

Summary

Suggested Readings

References

52 Pediatric Genitourinary Trauma

Renal Injuries

Indications for Renal Imaging

Imaging Studies for Diagnosis

Classification and Grading of Renal Injuries

Persistent or Delayed Bleeding

Operative

Ureteral Trauma

Bladder Injuries

Genital Injury in the Pediatric Population

References

Section G Oncology

53 Pediatric Urologic Oncology

Neuroblastoma

Wilms Tumor

References

54 Pediatric Urologic Oncology

Epidemiology and Syndromic Associations

Pathology and Molecular Biology

Presentation, Initial Evaluation and Management, Staging

Other Bladder Tumors

Female Genital Tract

Testicular Tumors

Paratesticular Rhabdomyosarcoma

Perineal Rhabdomyosarcoma

Suggested Readings

62 Molecular Genetics and Cancer Biology

- Tumor Suppressor Genes and Oncogenes
- Cell Cycle Deregulation
- DNA Methylation
- DNA Damage and Repair
- Genomic Alterations

Telomeres and Telomerase

Apoptosis

Stem Cells and Cancer

Checkpoint Inhibition

Microbiome and Cancer: the Metagenome

Suggested Readings

References

Part VI Reproductive and Sexual Function

63 Surgical, Radiographic, and Endoscopic Anatomy of the Male Reproductive System

Testis

Epididymis

Vas Deferens

Seminal Vesicles and Ejaculatory Ducts

Prostate

Urethra

Penis

Scrotum

Suggested Readings

References

64 Male Reproductive Physiology

- Hypothalamic-Pituitary-Gonadal Axis
- Epididymis
- Ductus (Vas) Deferens
- Seminal Vesicle and Ejaculatory Ducts
- Spermatozoa
- Summary
- Suggested Readings

Dedication

Dedicated to my wife, family, residents, and faculty, all of whom have supported me in this work in various and important ways and helped make this edition of Campbell-Walsh-Wein *possible.*

AP

For this edition of Campbell's *I would like to thank my spouse and my children for their unbelievable support during my career in urology. I would also like to thank my past and present residents and fellows for all that they have taught me about the importance of listening. I would like to recognize a few mentors who have taught me a great deal about the specialty and humanity: Dr. Herb Seybold, Dr. Marty Resnick, Dr. Joe Segura, Dr. Joseph Corriere, Dr. George Benson, Dr. Gerald Jordan, and Dr. Jay Smith.*

RD

To my mentors, whose reassuring voices forever guide me: Bill Catalona, Ralph Clayman, Alan Retik, and Pat Walsh.

LK

The privilege of compiling and editing this book makes us reflect on the vast body of knowledge and experience that makes up the field of urology, and the efforts and dedication of our predecessors and *mentors, to whom I dedicate this work. Without the examples, teaching, and inspiration (with not infrequent cajoling and correction), none of us would have been able to grow into who we are or participate in this textbook. For myself, these mentors have been many and varied, guiding me to this day in areas of clinical care, teaching, research, and mentoring. Some are no longer with us but they all continue to inspire.*

I also include my wife and children, who inspire, teach, and support me in so many ways. Their commitment has meant the world to me.

CP

Preface

Continuing in a great tradition of publishers, editors, and authors, we proudly present to you, our readers, the twelfth edition of the “Bible of Urology”—*Campbell-Walsh-Wein Urology*. Started in 1954 as *Campbell's Urology* and retitled *Campbell-Walsh Urology* in 2012, the present editors felt it was appropriate to honor Alan J. Wein, MD, PhD (Hon) for his many years of dedication to this text by adding his name to the previous chief editors. During his time as chief editor, Dr. Wein was responsible for keeping the textbook in pace with a rapidly growing field in medicine—for this diligence and dedication we are grateful.

As with previous editions, the twelfth edition presents many exciting advances in our use and understanding of technology, physiology, pharmacology, epidemiology, and pathophysiology while maintaining our basic classical urological knowledge.

We are dedicated to keeping the content of this textbook fresh and on the cutting edge of care. *CWW-12* adds 10 novel chapters and more than 150 first-time authors, including several new authors from international sites. *CWW-12* has 3 volumes, 162 chapters, 3706 pages, and more than 3000 illustrations.

The format continues to include color images, Key Points, Suggested Readings, boldfaced important text, and online linkable references to streamline the access and usefulness of the material. Additionally, as in previous editions, a companion Review book with questions and answers for each chapter is available separately under the leadership of Drs. Alan Wein and Thomas F. Kolon.

Volume I (54 chapters) covers basic urological evaluation, imaging and principles and fundamentals of surgery, endourology, and laparoscopy. Also in Volume I is a completely revamped and updated evaluation, the exstrophy-epispadias complex, pediatric stone disease, hypospadias, disorders of sexual development, and many more topics.

Volume II (50 chapters) covers infections within the urinary tract, sexually transmitted diseases, male reproduction, male infertility, erectile dysfunction, neoplasms/management of the testes and penis, medical/surgical management of urological stone disease, and many more topics.

Volume III (58 chapters) covers anatomy, physiology, pharmacology, pathophysiology, oncology, and surgery of the adrenal glands; all chapters covering diagnosis, physiology, and pathophysiology of female and male lower urinary tract disorders; all oncologic aspects (imaging, diagnosis, staging, treatment, and outcomes) of the bladder and prostate; urinary diversion; and physiology, diagnosis, and medical and surgical treatment of benign prostatic hyperplasia.

We all remain extremely proud once again to present you with this textbook and are especially thankful for our spouses and families who have put up with us during the months of review, editing, and proofing. We also give special thanks to the hundreds of authors whose time, expertise, and effort have made all of this possible. We would also like to thank our editorial support staff from Elsevier: Jennifer S. Ehlers (Senior Content Development Specialist) and Belinda Kuhn (Senior Content Strategist), who helped us to coordinate *CWW-12*.

We truly hope you will enjoy reading this textbook.

Department of Urology at University of Texas Southwestern Medical Center
Dallas, Texas

Peter R. Carroll MD, MPH
Professor and Chair, Urology
University of California, San Francisco
San Francisco, California

K. Clint Cary MD, MPH
Assistant Professor
Department of Urology
Indiana University
Indianapolis, Indiana

Erik P. Castle MD
Professor of Urology
Mayo Clinic Arizona
Phoenix, Arizona

Toby C. Chai MD
Professor and Chair, Department of Urology
Boston University School of Medicine
Chief of Urology
Boston Medical Center
Boston, Massachusetts

Charbel Chalouhy MD
Assistant Professor of Urology
Campus des Sciences Médicales
St. Joseph University
Beirut, Lebanon

Alicia H. Chang MD, MS
Instructor
Department of Internal Medicine/Infectious Diseases and Geographic Medicine
Stanford University School of Medicine
Stanford, California
Medical Consultant
Los Angeles County Tuberculosis Control Program
Los Angeles County Department of Public Health
Los Angeles, California

Christopher R. Chapple MD, FRCS (Urol)
Professor and Consultant Urologist
Department of Urology
The Royal Hallamshire Hospital, Sheffield Teaching Hospitals
Sheffield, South Yorkshire, United Kingdom

Thomas Chi MD
Associate Professor
Associate Chair for Clinical Affairs
Department of Urology

University of California–San Francisco
San Francisco, California

John P. Christodouleas MD, MPH
Professor of Radiation Oncology
Urologic Cancer Program
Penn Medicine
Philadelphia, Pennsylvania

Peter E. Clark MD
Professor and Chairman, Urology
Atrium Health
Chair, Urologic Oncology
Levine Cancer Institute
Charlotte, North Carolina

Douglass B. Clayton MD, FAAP
Assistant Professor
Urologic Surgery
Vanderbilt University
Nashville, Tennessee

Joshua A. Cohn MD
Assistant Professor of Urology
Department of Urology
Einstein Healthcare Network
Assistant Professor of Urology
Department of Surgery, Division of Urologic Oncology
Fox Chase Cancer Center
Philadelphia, Pennsylvania

Michael Joseph Conlin MD, MCR
Professor, Urology
Portland VA Medical Center
Professor, Urology
Oregon Health & Sciences University
Portland, Oregon

Christopher S. Cooper MD, FAAP, FACS
Professor
Department of Urology
University of Iowa
Associate Dean, Student Affairs and Curriculum
University of Iowa Carver College of Medicine
Iowa City, Iowa

Kimberly L. Cooper MD
Associate Professor of Urology
Columbia University Medical Center
New York, New York

Lawrence A. Copelovitch MD
Assistant Professor of Pediatrics
Department of Nephrology
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Hillary L. Copp MD
Associate Professor, Pediatric Urology
University of California–San Francisco
San Francisco, California

Nicholas G. Cost MD
Assistant Professor
Department of Surgery
Division of Urology
University of Colorado School of Medicine
Aurora, Colorado

Anthony J. Costello FRACS, MD
Professor, Urology
Royal Melbourne Hospital, Parkville Victoria
Victoria, Australia

Lindsey Cox MD
Assistant Professor of Urology

Medical University of South Carolina
Charleston, South Carolina

Paul L. Crispen MD
Associate Professor
Department of Urology
University of Florida
Gainesville, Florida

Juanita M. Crook MD, FRCPC
Professor, Radiation Oncology
University of British Columbia
Radiation Oncologist
Center for the Southern Interior
British Columbia Cancer Agency
Kelowna, British Columbia, Canada

Gerald Cunha PhD
Professor Emeritus, Urology
School of Medicine
University of California, San Francisco
San Francisco, California

Douglas M. Dahl MD, FACS
Associate Professor of Surgery
Harvard Medical School
Chief, Division of Urologic Oncology
Department of Urology
Massachusetts General Hospital
Boston, Massachusetts

Siamak Daneshmand MD
Associate Professor of Urology (Clinical Scholar)
Institute of Urology
University of Southern California, Los Angeles
Los Angeles, California

Casey A. Dauw MD

Assistant Professor, Urology
University of Michigan
Ann Arbor, Michigan

Shubha K. De MD, FRCSC
Assistant Professor
Department of Surgery
Division of Urology
University of Alberta
Edmonton, Alberta, Canada

Guarionex Joel DeCastro MD, MPH
Assistant Professor, Urology
Columbia University Medical Center;
Department of Urology
New York Presbyterian Hospital/Columbia University
New York, New York

Jean J.M.C.H. de la Rosette MD, PhD
Professor, Urology
AMC University Hospital
Amsterdam, Netherlands

Francisco T. Dénes MD, PhD
Associate Professor, Division of Urology
Chief, Pediatric Urology
University of São Paulo Medical School;
Hospital das Clínicas
São Paulo, Brazil

Dirk J.M.K. De Ridder MD, PhD, FEBU
Professor, Urology
University Hospitals KU Leuven
Leuven, Belgium

Mahesh R. Desai MS, FRCS
Chief Urologist and Managing Trustee
Department of Urology

Muljibhai Patel Urological Hospital, Nadiad
Gujarat, India

David Andrew Diamond MD
Urologist-in-Chief
Department of Urology
Boston Children's Hospital
Professor of Surgery (Urology)
Harvard Medical School
Boston, Massachusetts

Heather N. Di Carlo MD
Director, Pediatric Urology Research
Assistant Professor of Urology
Johns Hopkins Medicine
Baltimore, Maryland

Colin P.N. Dinney MD
Chairman and Professor
Department of Urology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Roger R. Dmochowski MD, MMHC, FACS
Professor, Urologic Surgery, Surgery and Gynecology
Program Director, Female Pelvic Medicine and Reconstructive Surgery
Vice Chair for Faculty Affairs and Professionalism
Section of Surgical Sciences
Associate Surgeon-in-Chief
Vanderbilt University Medical Center
Nashville, Tennessee

Charles G. Drake MD, PhD
Associate Professor of Oncology, Immunology, and Urology
James Buchanan Brady Urological Institute
Johns Hopkins University
Attending Physician
Department of Oncology

Johns Hopkins Kimmel Cancer Center
Baltimore, Maryland

Brian Duty MD
Associate Professor, Urology
Oregon Health & Science University
Portland, Oregon

James A. Eastham MD
Chief, Urology Service
Department of Surgery
Memorial Sloan-Kettering Cancer Center
Professor, Urology
Weill Cornell Medical Center
New York, New York

Scott Eggener MD
Professor, Surgery
University of Chicago
Chicago, Illinois

Mohamed Aly Elkoushy MD, MSc, PhD
Professor, Urology
Faculty of Medicine
Suez Canal University
Ismailia, Egypt

Jonathan Scott Ellison MD
Assistant Professor of Urology
Medical College of Wisconsin
Children's Hospital of Wisconsin
Milwaukee, Wisconsin

Sammy E. Elsamra MD
Assistant Professor of Surgery (Urology)
Department of Urology
Rutgers Robert Wood Johnson Medical School
Director of Robotic Surgical Services

Robert Wood Johnson University Hospital
RWJ-Barnabas Health
New Brunswick, New Jersey

Jonathan I. Epstein MD
Professor of Pathology, Urology, Oncology
The Reinhard Professor of Urological Pathology
Director of Surgical Pathology
The Johns Hopkins Medical Institutions
Baltimore, Maryland

Carlos R. Estrada MD, MBA
Associate Professor, Surgery
Harvard Medical School
Associate in Urology
Boston Children's Hospital
Boston, Massachusetts

Jairam R. Eswara MD
Assistant Surgeon
Division of Urology
Brigham and Women's Hospital
Boston, Massachusetts

Fernando A. Ferrer MD, FACS, FAAP
Professor of Urology
Department of Urology
Mount Sinai School of Medicine
New York, New York

Neil Fleshner MD, MPH, FRCSC
Professor of Surgery and Martin Barkin Chair
Department of Urology
University of Toronto
Surgeon, Uro-Oncology
University Health Network
Toronto, Ontario, Canada

Bryan Foster MD
Associate Professor
Department of Radiology
Oregon Health & Science University
Portland, Oregon

Richard S. Foster MD
Professor, Department of Urology
Indiana University
Indianapolis, Indiana

Pat F. Fulgham MD
Director of Surgical Oncology
Department of Urology
Texas Health Presbyterian Dallas
Dallas, Texas

Arvind P. Ganpule MS, DNB
Department of Urology
Muljibhai Patel Urological Hospital
Nadiad, Gujarat, India

Kris Gaston MD
Carolinas Medical Center
Charlotte, North Carolina

John P. Gearhart MD
The James Buchanan Brady Urological Institute
Johns Hopkins Medical Institutions
Baltimore, Maryland

Matthew T. Gettman MD
Professor and Vice-Chair, Urology
Mayo Clinic
Rochester, Minnesota

Reza Ghavamian MD
Eastern Regional Director of Urology

Department of Urology
Northwell Health
Greenlawn, New York
Professor of Urology
Zucker School of Medicine at Hofstra Northwell
New Hyde Park, New York

Bruce R. Gilbert MD, PhD
Professor of Urology
The Smith Institute for Urology
Zucker School of Medicine of Hofstra/Northwell
New Hyde Park, New York

Timothy D. Gilligan MD, MS, FASCO
Associate Professor of Medicine
Solid Tumor Oncology
Cleveland Clinic Lerner College of Medicine
Program Director, Hematology/Oncology Fellowship
Taussig Cancer Institute
Cleveland Clinic
Cleveland, Ohio

David A. Goldfarb MD
Professor of Surgery, CCLCM
Glickman Urological and Kidney Institute
Cleveland Clinic
Cleveland, Ohio

Marc Goldstein MD, DSc (hon), FACS
Matthew P. Hardy Distinguished Professor of Urology and Male Reproductive Medicine
Department of Urology and Institute for Reproductive Medicine
Weill Medical College of Cornell University
Surgeon-in-Chief, Male Reproductive Medicine, and Surgery
Department of Urology and Institute for Reproductive Medicine
New York Presbyterian Hospital–Weill Cornell Medical Center
New York, New York

Leonard G. Gomella MD, FACS
Professor and Chair
Department of Urology
Thomas Jefferson University
Philadelphia, Pennsylvania

Alex Gomelsky MD
B.E. Trichel Professor and Chairman
Department of Urology
Louisiana State University Health–Shreveport
Shreveport, Louisiana

Mark L. Gonzalgo MD, PhD
Professor and Vice Chairman, Urology
University of Miami Miller School of Medicine
Miami, Florida

Michael A. Gorin MD
Assistant Professor
Department of Urology
Johns Hopkins University School of Medicine
Baltimore, Maryland

Tamsin Greenwell MD, PhD
Consultant Urological Surgeon
University College London Hospitals
London, United Kingdom

Tomas L. Griebling MD, MPH
John P. Wolf 33-Degree Masonic Distinguished Professor of Urology
Department of Urology
The Landon Center on Aging
The University of Kansas
Kansas City, Kansas

Khurshid A. Guru MD
Chair, Department of Urology
Director of Robotic Surgery

Robert P. Huben Endowed Professor of Urologic Oncology
Roswell Park Comprehensive Cancer Center
Buffalo, New York

Thomas J. Guzzo MD, MPH
Assistant Professor of Urology
The Hospital of the University of Pennsylvania
University of Pennsylvania
Philadelphia, Pennsylvania

Jennifer A. Hagerty DO
Attending Physician
Departments of Surgery/Urology
Nemours/Alfred I. duPont Hospital for Children
Wilmington, Delaware
Assistant Professor
Departments of Urology and Pediatrics
Sidney Kimmel Medical College of Thomas Jefferson University
Philadelphia, Pennsylvania

Simon J. Hall MD
Professor
Smith Institute for Urology
Hofstra Northwell School of Medicine
Lake Success, New York

Barry Hallner MD
Associate Program Director, Female Pelvic Medicine & Reconstructive Surgery
Assistant Professor
Departments of OB/GYN and Urology
Louisiana State University Health
New Orleans School of Medicine
New Orleans, Louisiana

Ethan J. Halpern MD, MSCE
Professor of Radiology and Urology
Department of Radiology
Thomas Jefferson University

Philadelphia, Pennsylvania

Misop Han MD, MS
Professor, Urology and Oncology
Johns Hopkins Medicine
Baltimore, Maryland

Philip M. Hanno MD, MPH
Clinical Professor, Urology
Stanford University School of Medicine
Palo Alto, California

Siobhan M. Hartigan MD
Female Pelvic Medicine and Reconstructive Surgery Fellow
Department of Urology
Vanderbilt University Medical Center
Nashville, Tennessee

Christopher J. Hartman MD
Assistant Professor of Urology
The Smith Institute for Urology
Northwell Health System
Long Island City, New York

Hashim Hashim MBBS, MRCS (Eng), MD, FEBU, FRCS (Urol)
Consultant Urological Surgeon
Honorary Professor
Director of the Urodynamics Unit
Bristol Urological Institute
Southmead Hospital
Bristol, United Kingdom

Dorota J. Hawksworth MD, MBA
Director of Andrology and Male Sexual Health
Department of Urology
Walter Reed National Military Medical Center
Bethesda, Maryland

Sarah Hazell MD
Radiation Oncology Resident
Department of Radiation Oncology and Molecular Radiation Sciences
Johns Hopkins University School of Medicine
Baltimore, Maryland

John P.F.A. Heesakkers MD, PhD
Urologist
Radboudumc
Nijmegen, Netherlands

Sevann Helo MD
Southern Illinois University School of Medicine
Division of Urology
Springfield, Illinois

Amin S. Herati MD
Assistant Professor of Urology
Department of Urology
The James Buchanan Brady Urological Institute
Johns Hopkins University School of Medicine
Assistant Professor
Gynecology and Obstetrics
Johns Hopkins University School of Medicine
Baltimore, Maryland

C.D. Anthony Herndon MD, FAAP, FACS
Professor of Surgery
Director of Pediatric Urology
Surgeon-in-Chief, Children's Hospital of Richmond
Department of Urology
Virginia Commonwealth University
Richmond, Virginia

Piet Hoebeke MD, PhD
Professor, Urology
Dean, Faculty of Medicine and Health Sciences
Ghent University

Ghent, Belgium

David M. Hoenig MD
Professor and Chief
North Shore University Hospital
Smith Institute for Urology
North Shore-LIJ-Hofstra University
Lake Success, New York

Michael Hsieh MD, PhD
Stirewalt Endowed Director
Biomedical Research Institute
Rockville, Maryland
Associate Professor, Urology
George Washington University
Washington, DC

Valerio Iacovelli MD
Urology Unit
University of Rome Tor Vergata
San Carlo di Nancy General Hospital
GVM Care and Research
Rome, Italy

Stephen V. Jackman MD
Professor, Urology
University of Pittsburgh
Pittsburgh, Pennsylvania

Joseph M. Jacob MD, MCR
Assistant Professor, Urology
SUNY Upstate Medical Center
Syracuse, New York

Micah A. Jacobs MD, MPH
Department of Urology
University of Texas Southwestern Medical School
Dallas, Texas

Thomas W. Jarrett MD
Professor and Chairman, Urology
George Washington University
Washington, DC

Gerald H. Jordan MD, FACS, FAAP (Hon), FRCS (Hon)
Associate Professor, Urology
Eastern Virginia Medical School
Norfolk, Virginia

Martin Kaefer MD
Professor, Urology
Indiana University School of Medicine
Indianapolis, Indiana

Kamaljot S. Kaler MD
Clinical Assistant Professor
Section of Urology
Department of Surgery
University of Calgary
Calgary, Alberta, Canada

Panagiotis Kallidonis MD, MSc, PhD, FEBU
Consultant Urological Surgeon
Department of Urology
University of Patras
Patras, Greece

Steven Kaplan MD
Professor and Director
The Men's Health Program
Department of Urology
Icahn School of Medicine at Mount Sinai
New York, New York

Max Kates MD
Assistant Professor, Urology
Johns Hopkins Medical Institutions

Baltimore, Maryland

Melissa R. Kaufman MD, PhD
Associate Professor, Urologic Surgery
Vanderbilt University
Nashville, Tennessee

Louis R. Kavoussi MD, MBA
Professor and Chair
Department of Urology
Zucker School of Medicine at Hofstra/Northwell
Hempstead, New York
Chairman of Urology
The Arthur Smith Institute for Urology
Lake Success, New York

Parviz K. Kavoussi MD, FACS
Reproductive Urologist
Department of Urology
Austin Fertility and Reproductive Medicine
Adjunct Assistant Professor
Psychology: Neuroendocrinology and Motivation
University of Texas at Austin
Austin, Texas

Miran Kenk PhD
University Health Network
Toronto, Canada

Mohit Khera MD, MBA, MPH
Professor of Urology
Scott Department of Urology
Baylor College of Medicine
Houston, Texas

Antoine E. Khoury MD, FRCSC, FAAP
Walter R. Schmid Professor of Pediatric Urology
Head of Pediatric Urology

Children's Hospital of Orange County
Orange, California

Eric A. Klein MD
Chairman, Glickman Urological and Kidney Institute
Cleveland Clinic
Cleveland, Ohio

Laurence Klotz MD, FRCSC
Professor, Surgery
University of Toronto
Urologist
Sunnybrook Health Sciences Centre
Toronto, Ontario, Canada

Bodo Egon Knudsen MD, FRCSC
Associate Professor
Vice Chair Clinical Operations
Department of Urology
Wexner Medical Center
The Ohio State University
Columbus, Ohio

Kathleen C. Kobashi MD
Section Head, Urology and Renal Transplantation
Virginia Mason Medical Center
Seattle, Washington

Chester J. Koh MD
Associate Professor of Urology (Pediatric)
TCH Department of Surgery
Scott Department of Urology
Baylor College of Medicine
Texas Children's Hospital
Houston, Texas

Ervin Kocjancic MD
Professor of Urology

Department of Urology
University of Illinois Health and Science
Chicago, Illinois

Badrinath R. Konety MD, MBA
Professor and Chair, Dougherty Family Chair in UroOncology
Associate Director for Clinical Affairs and Clinical Research
Masonic Cancer Center;
Department of Urology
University of Minnesota
Minneapolis, Minnesota

Casey E. Kowalik MD
Department of Urologic Surgery
Vanderbilt University
Nashville, Tennessee

Martin A. Koyle MD, FAAP, FACS, FRCSC, FRCS (Eng)
Division Head, Pediatric Urology
Women's Auxiliary Chair in Urology and Regenerative Medicine
Hospital for Sick Children
Professor of Surgery
University of Toronto
Toronto, Ontario, Canada

Amy E. Krambeck MD
Michael O. Koch Professor of Urology
Indiana University
Indianapolis, Indiana

Jessica E. Kreshover MD, MS
Assistant Professor
Arthur Smith Institute for Urology
Donald and Barbara Zucker School of Medicine at Hofstra-Northwell
Lake Success, New York

Venkatesh Krishnamurthi MD
Director, Kidney/Pancreas Transplant Program

Glickman Urological and Kidney Institute, Transplant Center
Cleveland Clinic Foundation
Cleveland, Ohio

Ryan M. Krlin MD
Assistant Professor of Urology
Department of Urology
Louisiana State University
New Orleans, Louisiana

Alexander Kutikov MD, FACS
Professor and Chief, Urologic Oncology
Fox Chase Cancer Center
Philadelphia, Pennsylvania

Jaime Landman MD
Professor of Urology and Radiology
Chairman, Department of Urology
University of California Irvine
Orange, California

Brian R. Lane MD, PhD
Chief, Urology
Spectrum Health
Associate Professor
Michigan State University College of Human Medicine
Grand Rapids, Michigan

David A. Leavitt MD
Assistant Professor, Urology
Vattikuti Urology Institute
Henry Ford Health System
Detroit, Michigan

Eugene K. Lee MD
Assistant Professor, Urology
University of Kansas Medical Center
Kansas City, Kansas

Gary E. Lemack MD
Professor of Urology and Neurology
University of Texas Southwestern Medical Center
Dallas, Texas

Thomas Sean Lendvay MD, FACS
Professor, Urology
University of Washington
Professor, Pediatric Urology
Seattle Children's Hospital
Seattle, Washington

Herbert Lepor MD
Professor and Martin Spatz Chairman
Department of Urology
NYU School of Medicine
Chief, Urology
NYU Langine Health System
New York, New York

Evangelos Liatsikos MD, PhD
Professor, Urology
University of Patras
Patras, Greece

Sey Kiat Lim MBBS, MRCS (Edinburgh), MMed (Surgery), FAMS (Urology)
Associate Consultant, Urology
Changi General Hospital
Singapore

W. Marston Linehan MD
Chief, Urologic Oncology Branch
National Cancer Institute
National Institutes of Health
Bethesda, Maryland

Richard Edward Link MD, PhD

Carlton-Smith Chair in Urologic Education
Associate Professor of Urology
Director, Division of Endourology and Minimally Invasive Surgery
Scott Department of Urology
Baylor College of Medicine
Houston, Texas

Jen-Jane Liu MD
Director of Urologic Oncology
Assistant Professor
Department of Urology
Oregon Health & Science University
Portland, Oregon

Stacy Loeb MD, MSc
Assistant Professor, Urology and Population Health
New York University and Manhattan Veterans Affairs
New York, New York

Christopher J. Long MD
Assistant Professor of Urology
Department of Surgery
Division of Urology
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Roberto Iglesias Lopes MD, PhD
Assistant Professor
Division of Urology
Department of Surgery
University of São Paulo Medical School
São Paulo, Brazil

Armando J. Lorenzo MD, MSc, FRCSC, FAAP, FACS
Staff Paediatric Urologist
Department of Surgery
Division of Urology
Hospital for Sick Children

Associate Professor
Department of Surgery
Division of Urology
University of Toronto
Toronto, Ontario, Canada

Yair Lotan MD
Professor
Department of Urology
University of Texas Southwestern Medical Center
Dallas, Texas

Alvaro Lucioni MD
Department of Urology
Virginia Mason Medical Center
Seattle, Washington

Tom F. Lue MD, ScD (Hon), FACS
Professor of Urology
University of California–San Francisco
San Francisco, California

Nicolas Lumen MD, PhD
Professor, Urology
Ghent University Hospital
Ghent, Belgium

Marcos Tobias Machado MD, PhD
Head, Urologic Oncology Section
Department of Urology
Faculdade de Medicina do ABC, Santo André
São Paulo, Brazil

Stephen D. Marshall MD
Attending Physician
Laconia Clinic Department of Urology
Lakes Region General Hospital
Laconia, New Hampshire

Aaron D. Martin MD, MPH
Associate Professor
Department of Urology
Louisiana State University Health Sciences Center;
Pediatric Urology
Children's Hospital New Orleans
New Orleans, Louisiana

Laura M. Martinez MD
Instructor in Clinical Urology
Houston Methodist
Houston, Texas

Timothy A. Masterson MD
Associate Professor, Urology
Indiana University Medical Center
Indianapolis, Indiana

Surena F. Matin MD
Professor
Department of Urology
The University of Texas M.D. Anderson Cancer Center
Medical Director
Minimally Invasive New Technology in Oncologic Surgery (MINTOS)
The University of Texas M.D. Anderson Cancer Center
Houston, Texas

Brian R. Matlaga MD, MPH
Professor
James Buchanan Brady Urological Institute
Johns Hopkins Medical Institutions
Baltimore, Maryland

Kurt A. McCammon MD, FACS
Devine Chair in Genitourinary Reconstructive Surgery
Chairman and Program Director
Professor
Department of Urology

Eastern Virginia Medical School
Norfolk, Virginia

James M. McKiernan MD
Chairman and Professor, Urology
Columbia University Medical Center/NYPH
New York, New York

Chris G. McMahon MBBS, FAChSHP
Director
Australian Centre for Sexual Health
Sydney, New South Wales, Australia

Kevin T. McVary MD, FACS
Professor and Chairman
Division of Urology
Department ofSurgery
Southern Illinois University School of Medicine
Springfield, Illinois

Luis G. Medina MD
Medical Doctor and Researcher
Department of Urology
University of Southern California
Los Angeles, California

Kirstan K. Meldrum MD
Professor
Department of Surgery
Central Michigan University
Saginaw, Michigan

Matthew J. Mellon MD, FACS
Associate Professor, Urology
Indiana University
Indianapolis, Indiana

Maxwell V. Meng MD

Professor, Urology
Chief, Urologic Oncology
University of California–San Francisco
San Francisco, California

David Mikhail MD, FRCSC
Endourology Fellow
Department of Urology
Arthur Smith Institute for Urology/Northwell Health
New Hyde Park, New York

Nicole L. Miller MD
Associate Professor
Department of Urologic Surgery
Vanderbilt University Medical Center
Nashville, Tennessee

Alireza Moinzadeh MD
Director of Robotic Surgery
Institute of Urology
Lahey Hospital & Medical Center
Burlington, Massachusetts
Assistant Professor, Urology
Tufts University School of Medicine
Boston, Massachusetts

Robert M. Moldwin MD
Professor of Urology
The Arthur Smith Institute for Urology
Hofstra Northwell School of Medicine
Lake Success, New York

Manoj Monga MD, FACS
Director, Stevan Streem Center for Endourology & Stone Disease
Department of Urology
Cleveland Clinic
Cleveland, Ohio

Francesco Montorsi MD, FRCS (Hon)
Professor and Chairman, Urology
Vita-Salute San Raffaele University
Milan, Italy

Daniel M. Moreira MD, MHS
Assistant Professor, Urology
University of Illinois at Chicago
Chicago, Illinois

Allen F. Morey MD, FACS
Professor, Urology
University of Texas Southwestern Medical Center
Dallas, Texas

Todd M. Morgan MD
Associate Professor
Department of Urology
University of Michigan
Ann Arbor, Michigan

John J. Mulcahy MD, PhD, FACS
Clinical Professor, Urology
University of Alabama
Birmingham, Alabama

Ravi Munver MD, FACS
Vice Chairman
Department of Urology
Hackensack University Medical Center
Professor of Surgery (Urology)
Department of Urology
Seton Hall-Hackensack Meridian School of Medicine
Hackensack, New Jersey

Stephen Y. Nakada MD, FACS, FRCS (Glasg.)
Professor and Chairman, The David T. Uehling Chair of Urology
Department of Urology

University of Wisconsin School of Medicine and Public Health
Professor and Chairman
Department of Urology
University of Wisconsin Hospital and Clinics
Madison, Wisconsin

Neema Navai MD
Assistant Professor, Urology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Diane K. Newman DNP, ANP-BC, FAAN
Adjunct Professor of Urology in Surgery
Division of Urology
Perelman School of Medicine
Research Investigator Senior
Perelman School of Medicine
University of Pennsylvania
Philadelphia, Pennsylvania

Craig Stuart Niederberger MD, FACS
Clarence C. Saelhof Professor and Head
Department of Urology
University of Illinois at Chicago College of Medicine
Professor, Bioengineering
University of Illinois at Chicago College of Engineering
Chicago, Illinois

Victor W. Nitti MD
Professor of Urology and Obstetrics & Gynecology
Shlomo Raz Chair in Urology
Chief, Division of Female Pelvic Medicine and Reconstructive Surgery
David Geffen School of Medicine at UCLA
Los Angeles, California

Samuel John Ohlander MD
Assistant Professor, Urology
University of Illinois at Chicago

Chicago, Illinois

L. Henning Olsen MD, DMSc
Professor, Urology
Section of Pediatric Urology
Aarhus University Hospital
Skejby, Denmark
Professor
Institute of Clinical Medicine
Aarhus University
Aarhus, Denmark

Aria F. Olumi MD
Professor of Surgery/Urology
Department of Urologic Surgery
Beth Israel Deaconess Medical Center
Harvard Medical School
Boston, Massachusetts

Nadir I. Osman MBChB (Hons), MRCS
Department of Urology
Royal Hallmashire Hospital
Sheffield, South Yorkshire, United Kingdom

Brandon J. Otto MD
Assistant Professor, Urology
University of Florida
Gainesville, Florida

Priya Padmanabhan MD, MPH
Assistant Professor, Pelvic Reconstruction and Voiding Dysfunction
The University of Kansas
Kansas City, Kansas

Rodrigo Lessi Pagani MD
Assistant Professor, Urology
University of Illinois at Chicago
Chicago, Illinois

Lance C. Pagliaro MD
Professor
Department of Genitourinary Medical Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Ganesh S. Palapattu MD
Chief of Urologic Oncology
Associate Professor, Urology
University of Michigan
Ann Arbor, Michigan

Drew A. Palmer MD
Endourology Fellow
Department of Urology
University of North Carolina at Chapel Hill
Chapel Hill, North Carolina

Jeffrey S. Palmer MD, FACS, FAAP
Director, Pediatric and Adolescent Urology Institute
Cleveland, Ohio

Lane S. Palmer MD, FACS
Professor and Chief, Pediatric Urology
Cohen Children's Medical Center of New York
Zucker School of Medicine of Hofstra/Northwell
Long Island, New York

Meyeon Park MD, MAS
Assistant Professor in Residence, Medicine
University of California–San Francisco
San Francisco, California

Department of Urology
University of Kansas Health System
Kansas City, Kansas

Alan W. Partin MD, PhD
The Jakurski Family Director
Urologist-in-Chief
Chairman, Department of Urology
Professor, Departments of Urology, Oncology and Pathology
Johns Hopkins Medical Institutions
Baltimore, Maryland

Roshan M. Patel MD
Clinical Instructor
Department of Urology
University of California–Irvine
Orange, California

Margaret S. Pearle MD, PhD
Professor, Urology, Internal Medicine
University of Texas Southwestern Medical Center
Dallas, Texas

David F. Penson MD, MPH
Professor and Chair, Urologic Surgery
Vanderbilt University
Director
Center for Surgical Quality and Outcomes Research
Vanderbilt Institute for Medicine and Public Health
Nashville, Tennessee

Craig A. Peters MD
Chief, Pediatric Urology
Children's Health System Texas
Professor of Urology
University of Texas Southwestern Medical Center
Dallas, Texas

Curtis A. Pettaway Sr., MD
Professor
Department of Urology
University of Texas M.D. Anderson Cancer Center

Houston, Texas

Janey R. Phelps MD
Department of Anesthesia
University of North Carolina School of Medicine
Chapel Hill, North Carolina

Ryan Phillips MD, PhD
Resident Physician
Radiation Oncology and Molecular Radiation Sciences
Johns Hopkins University School of Medicine
Baltimore, Maryland

Phillip M. Pierorazio MD
Associate Professor
Urology and Oncology
Brady Urological Institute and Department of Urology
Johns Hopkins University
Baltimore, Maryland

Hans G. Pohl MD, FAAP
Associate Professor, Urology and Pediatrics
Children's National Medical Center
Washington, DC

Thomas J. Polascik MD
Professor, Urologic Surgery
Duke Comprehensive Cancer Center
Duke Cancer Institute
Durham, North Carolina

Michel Pontari MD
Professor and Vice-Chair, Urology
Lewis Katz School of Medicine at Temple University
Philadelphia, Pennsylvania

John C. Pope IV, MD
Professor, Urologic Surgery and Pediatrics

Vanderbilt University Medical Center
Nashville, Tennessee

Jay D. Raman MD, FACS
Professor and Chief, Urology
Penn State Health Milton S. Hershey Medical Center
Hershey, Pennsylvania

Ranjith Ramasamy MD
Director, Reproductive Urology
Department of Urology
University of Miami
Miami, Florida

Ardeshir R. Rastinehad DO, FACOS
Director, Focal Therapy and Interventional Urology
Associate Professor of Radiology and Urology
Icahn School of Medicine at Mount Sinai
New York, New York

Yazan F.H. Rawashdeh MD, PhD
Consultant Pediatric Urologist
Section of Pediatric Urology
Aarhus University Hospital
Aarhus, Denmark

Pramod P. Reddy MD
The Curtis Sheldon and Jeffrey Wacksman Chair of Pediatric Urology
Division of Pediatric Urology
Cincinnati Children's Hospital Medical Center
Professor of Surgery
Division of Urology
University of Cincinnati College of Medicine
Cincinnati, Ohio

W. Stuart Reynolds MD, MPH
Assistant Professor, Urologic Surgery
Vanderbilt University

Nashville, Tennessee

Koon Ho Rha MD, PhD, FACS
Professor
Department of Urology
Urological Science Institute
Yonsei University College of Medicine
Seoul, Republic of Korea

Lee Richstone MD
Chief, Urology
Long Island Jewish Medical Center
Lake Success, New York
System Vice Chairman, Urology
Northwell Health
New York, New York

Stephen Riggs MD
Urologic Oncology
Levine Cancer Institute
Charlotte, North Carolina

Richard C. Rink MD, FAAP, FACS
Emeritus Professor, Pediatric Urology
Riley Hospital for Children Indiana University School of Medicine
Faculty, Pediatric Urology
Peyton Manning Children's Hospital St. Vincent
Indianapolis, Indiana

Michael L. Ritchey MD
Professor, Urology
Mayo Clinic College of Medicine
Phoenix, Arizona

Claus G. Roehrborn MD
Professor and Chairman, Urology
University of Texas Southwestern Medical Center
Dallas, Texas

Ashley Evan Ross MD, PhD
Assistant Professor, Urology
Johns Hopkins Brady Urological Institute
Baltimore, Maryland

Sherry S. Ross MD
Department of Anesthesia
The University of North Carolina at Chapel Hill
Chapel Hill, North Carolina

Christopher C. Roth MD
Associate Professor of Urology
Louisiana State University Health Sciences Center;
Pediatric Urology
Childrens Hospital New Orleans
New Orleans, Louisiana

Kyle O. Rove MD
Urologist
St. Louis Children's Hospital
Washington University
St. Louis, Missouri

Eric S. Rovner MD
Professor
Department of Urology
Medical University of South Carolina
Charleston, South Carolina

Steven P. Rowe MD
Assistant Professor
Department of Radiology
Johns Hopkins University
Baltimore, Maryland

Matthew P. Rutman MD
Associate Professor, Urology
Columbia University College of Physicians and Surgeons

New York, New York

Simpa S. Salami MD, MPH
Assistant Professor
Department of Urology
University of Michigan
Ann Arbor, Michigan

Andrea Salonia MD, PhD
Director, Urological Research Institute
Milan, Italy

Edward M. Schaeffer MD, PhD
Professor and Chair, Urology
Northwestern University
Chicago, Illinois

Bruce J. Schlomer MD
Assistant Professor, Urology
University of Texas Southwestern Medical Center
Dallas, Texas

Michael J. Schwartz MD, FACS
Associate Professor of Urology
The Smith Institute for Urology
Hofstra Northwell School of Medicine
New Hyde Park, New York

Allen D. Seftel MD
Professor of Urology
Department of Surgery
Cooper Medical School of Rowan University
Chief, Division of Urology
Cooper University Health Care
Camden, New Jersey

Rachel Selekman MD, MAS
Instructor, Surgery

Division of Pediatric Urology
Children's National Medical Center
Washington, DC

Abhishek Seth MD
Assistant Professor, Urology
Baylor College of Medicine
Houston, Texas

Karen S. Sfanos PhD
Assistant Professor, Pathology
Johns Hopkins University School of Medicine
Baltimore, Maryland

Paras H. Shah MD
Urologic Oncology
Department of Urology
Mayo Clinic
Rochester, Minnesota

Mohammed Shahait MBBS
Clinical Instructor of Urology
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

Robert C. Shamberger MD
Chief of Surgery
Boston Children's Hospital
Robert E. Gross Professor of Surgery
Harvard Medical School
Boston, Massachusetts

Alan W. Shindel MD, MAS
Associate Professor, Urology
University of California, San Francisco
San Francisco, California

Aseem Ravindra Shukla MD

Director of Minimally Invasive Surgery
Department of Pediatric Urology
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Jay Simhan MD, FACS
Vice Chairman, Department of Urology
Einstein Healthcare Network
Associate Professor of Urology
Temple Health/Fox Chase Cancer Center
Philadelphia, Pennsylvania

Brian Wesley Simons DVM, PhD
Assistant Professor, Urology
Johns Hopkins University School of Medicine
Baltimore, Maryland

Eila C. Skinner MD
Professor and Chair, Urology
Stanford University
Stanford, California

Armine K. Smith MD
Assistant Professor
Brady Urological Institute
Johns Hopkins University
Assistant Professor, Urology
George Washington University
Washington, DC

Daniel Y. Song MD
Associate Professor, Radiation Oncology and Molecular Radiation Sciences
Johns Hopkins University School of Medicine
Baltimore, Maryland

Rene Sotelo MD
Physician, Surgeon, Urologist
Minimally Invasive and Robotic Surgery Center

Instituto Medico La Floresta, Caracas
Miranda, Venezuela

Michael W. Sourial MD, FRCSC
Assistant Professor, Urology
Wexner Medical Center
The Ohio State University
Columbus, Ohio

Anne-Françoise Spinoit MD, PhD
Pediatric and Reconstructive Urologist
Department of Urology
Ghent University Hospital
Ghent, Belgium

Arun K. Srinivasan MD
Pediatric Urologist
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Ramaprasad Srinivasan MD, PhD
Head, Molecular Cancer Section
Urologic Oncology Branch
Center for Cancer Research
National Cancer Institute
National Institutes of Health
Bethesda, Maryland

Irina Stanasel MD
Assistant Professor, Urology
University of Texas Southwestern Medical Center/Children's Health
Dallas, Texas

Andrew J. Stephenson MD, MBA, FRCSC, FACS
Associate Professor of Surgery
Department of Urology
Cleveland Clinic Lerner College of Medicine
Case Western Reserve University

Director, Urologic Oncology
Glickman Urological and Kidney Institute
Cleveland Clinic
Cleveland, Ohio

Julie N. Stewart MD
Assistant Professor
Department of Urology
Houston Methodist Hospital
Houston, Texas

John Stites MD
Minimally Invasive and Robotic Urologic Surgery
Hackensack University Medical Center
Hackensack, New Jersey

Douglas W. Storm MD, FAAP
Assistant Professor
Department of Urology
University of Iowa Hospitals and Clinics
Iowa City, Iowa

Douglas William Strand PhD
Assistant Professor, Urology
University of Texas Southwestern Medical Center
Dallas, Texas

Li-Ming Su MD
David A. Cofrin Professor of Urologic Oncology
Chairman, Department of Urology
University of Florida College of Medicine
Gainesville, Florida

Chandru P. Sundaram MD, FACS, FRCS (Eng)
Professor, Urology
Indiana University School of Medicine
Program Director and Director of Minimally Invasive Surgery
Department of Urology

Indiana University School of Medicine
Indianapolis, Indiana

Samir S. Taneja MD
James M. and Janet Riha Neissa Professor of Urologic Oncology
Departments of Urology and Radiology
NYU Langone Medical Center
New York, New York

Nikki Tang MD
Assistant Professor, Dermatology
Johns Hopkins University
Baltimore, Maryland

Gregory E. Tasian MD, MSc, MSCE
Assistant Professor, Urology and Epidemiology
University of Pennsylvania–Perelman School of Medicine
Attending Physician, Urology
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Kae Jack Tay MBBS, MRCS (Ed), MMed (Surgery), MCI, FAMS (Urology)
Consultant
Department of Urology
Singapore General Hospital
SingHealth Duke-NUS Academic Medical Center
Singapore

John C. Thomas MD, FAAP, FACS
Associate Professor of Urologic Surgery
Division of Pediatric Urology
Monroe Carell Jr. Children's Hospital at Vanderbilt
Nashville, Tennessee

J. Brantley Thrasher MD, FACS
William L Valk Distinguished Professor
Department of Urology
University of Kansas Medical Center

Kansas City, Kansas

Edouard J. Trabulsi MD, FACS
Professor
Department of Urology
Kimmel Cancer Center
Sidney Kimmel Medical College
Thomas Jefferson University
Philadelphia, Pennsylvania

Chad R. Tracy MD
Assistant Professor, Urology
University of Iowa
Iowa City, Iowa

Paul J. Turek MD, FACS, FRSM
Director
The Turek Clinic
San Francisco, California

Mark D. Tyson MD, MPH
Department of Urology
Mayo Clinic College of Medicine and Science
Phoenix, Arizona

Robert G. Uzzo MD, FACS
Professor and Chairman
Department of Surgery
The G. Willing “Wing” Pepper Professor in Cancer Research
Adjunct Professor of Bioengineering
Temple University College of Engineering
Fox Chase Cancer Center–Temple University Health System
Lewis Katz School of Medicine
Philadelphia, Pennsylvania

Brian A. VanderBrink MD
Urologist
Division of Urology

Cincinnati Children's Hospital
Cincinnati, Ohio

Alex J. Vanni MD, FACS
Associate Professor
Department of Urology
Lahey Hospital and Medical Center
Burlington, Massachusetts

David J. Vaughn MD
Professor of Medicine
Division of Hematology/Oncology
Department of Medicine
Abramsom Cancer Center at the University of Pennsylvania
Philadelphia, Pennsylvania

Vijaya M. Vemulakonda MD, JD
Associate Professor of Pediatric Urology
Division of Urology
Department of Surgery
University of Colorado School of Medicine
Aurora, Colorado

Manish A. Vira MD
Vice Chair of Urologic Research
Smith Institute for Urology
Northwell Health
Lake Success, New York
Associate Professor of Urology
Zucker School of Medicine of Hofstra/Northwell
Hempstead, New York

Ramón Virasoro MD
Associate Professor, Urology
Eastern Virginia Medical School
Norfolk, Virginia
Fellowship Director, Urology
Universidad Autonoma de Santo Domingo

Santo Domingo, Dominican Republic

Alvin C. Wee MD
Surgical Director, Kidney Transplantation
Glickman Urological and Kidney Institute
Cleveland Clinic
Cleveland, Ohio

Elias Wehbi MD, FRCSC
Assistant Professor
Department of Urology–Division of Pediatric Urology
University of California Irvine
Orange, California

Alan J. Wein MD, PhD (Hon), FACS
Founders Professor and Emeritus Chief of Urology
Co-Director, Urologic Oncology Program
Co-Director, Voiding Function and Dysfunction Program
Division of Urology
Penn Medicine, Perelman School of Medicine
Philadelphia, Pennsylvania

Dana A. Weiss MD
Assistant Professor, Urology
University of Pennsylvania
Attending Physician, Urology
The Childrens Hospital of Philadelphia
Philadelphia, Pennsylvania

Jeffrey P. Weiss MD, FACS
Professor and Chair
Department of Urology
SUNY Downstate College of Medicine
Brooklyn, New York

Robert M. Weiss MD
Donald Guthrie Professor of Surgery/Urology
Yale University School of Medicine

New Haven, Connecticut

Charles Welliver Jr., MD
Assistant Professor
Division of Urology
Albany Medical College
Albany, New York

Hunter Wessells MD, FACS
Professor and Nelson Chair
Department of Urology
Affiliate Member
Harborview Injury Prevention and Research Center
University of Washington
Seattle, Washington

Duncan T. Wilcox MD, MBBS
Surgeon-in-Chief
Ponzio Family Chair of Pediatric Urology
Department of Pediatric Urology
Children's Hospital Colorado
Aurora, Colorado

Jack Christian Winters MD, FACS
Professor and Chairman, Urology
Louisiana State University Health Sciences Center
New Orleans, Louisiana

Anton Wintner MD
Instructor in Surgery
Harvard Medical School
Assistant in Urology
Massachusetts General Hospital
Boston, Massachusetts

J. Stuart Wolf Jr., MD, FACS
Professor and Associate Chair for Clinical Integration and Operations
Departments of Surgery and Perioperative Care

Dell Medical School
The University of Texas at Austin
Austin, Texas

Christopher E. Wolter MD
Assistant Professor, Urology
Mayo Clinic Arizona
Phoenix, Arizona

Dan Wood PhD
Consultant Urologist in Adolescent and Reconstructive Surgery
The University College Hospitals
London, United Kingdom

Michael E. Woods MD
Associate Professor, Urology
University of North Carolina
Chapel Hill, North Carolina

Hailiu Yang MD
Department of Urology
Cooper Health
New York, New York

Richard Nithiphaisal Yu MD, PhD
Pediatric Urology Attending
Department of Urology
Boston Children's Hospital
Boston, Massachusetts

Joseph Zabell MD
Assistant Professor
Department of Urology
University of Minnesota
Minneapolis, Minnesota

Mark R. Zaontz MD
Professor of Clinical Urology in Surgery

Perelman School of Medicine
University of Pennsylvania
Attending Physician, Urology
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Rebecca S. Zee MD, PhD
Chief Resident of Urology
University of Virginia School of Medicine
Charlottesville, Virginia

Video Contents

- PART I **Clinical Decision Making**
  - Chapter 4 **Urinary Tract Imaging: Basic Principles of Urologic Ultrasonography**
    - **Video 4.1 Importance of survey scans.** *Courtesy Bruce R. Gilbert and Pat F. Fulgham*
    - **Video 4.2 Perineal ultrasound.** *Courtesy Bruce R. Gilbert and Pat F. Fulgham*
- PART II **Basics of Urologic Surgery**
  - Chapter 11 **Lower Urinary Tract Catheterization**
    - **Video 11.1 Female urethral catheterization.** *Courtesy Jay Sulek and Chandru Sundaram*
    - **Video 11.2 Male urethral catheterization.** *Courtesy Jay Sulek and Chandru P. Sundaram*
  - Chapter 12 **Fundamentals of Upper Urinary Tract Drainage**
    - **Video 12.1 “Eye-of-the-needle” fluoroscopically guided antegrade access into the upper urinary tract collecting system.** *Courtesy J.*

Stuart Wolf, Jr.

Chapter 13 **Principles of Urologic Endoscopy**

Video 13.1 Ureteroscopy and retrograde ureteral access. *Courtesy Ben H. Chew and John D. Denstedt*

PART III **Pediatric Urology**

SECTION A Development and Prenatal Urology

Chapter 22 **Perinatal Urology**

Video 22.1 Prenatal urinary tract dilation of the fetal kidneys. *Courtesy C.D. Anthony Herndon and Rebecca S. Zee*

Video 22.2 Fetal measurement of amniotic fluid index. *Courtesy C.D. Anthony Herndon and Rebecca S. Zee*

Video 22.3 Fetal ultrasound documenting multicystic dysplastic kidney. *Courtesy C.D. Anthony Herndon and Rebecca S. Zee*

SECTION B Basic Principles

Chapter 23 **Urologic Evaluation of the Child**

Video 23.1 Male examination. *Courtesy Rachel Selekman and Hillary Copp*

Video 23.2 Female examination. *Courtesy Rachel Selekman and Hillary Copp*

Chapter 27 **Principles of Laparoscopic and Robotic Surgery in Children**

Video 27.1 Robotic-assisted ureteral reimplantation. *Courtesy Thomas Sean Lendvay and Jonathan Ellison*
Video 27.2 Robotic-assisted ureteroureterostomy. *Courtesy Thomas Sean Lendvay and Jonathan Ellison*
Video 27.3 Robotic-assisted buccal graft pyeloureteroplasy with omental quilting. *Courtesy Thomas Sean Lendvay and Jonathan Ellison*
Video 27.4 Robotic-assisted ureteral polyp resection. *Courtesy Thomas Sean Lendvay and Jonathan Ellison*
SECTION C Lower Urinary Tract Conditions
Chapter 32 Prune-Belly Syndrome
Video 32.1 Abdominoplasty in prune-belly syndrome. *Courtesy Francisco T. Dénes and Roberto Iglesias Lopes*
Chapter 33 Posterior Urethral Valves
Video 33.1 Cystoscopic incision and ablation of posterior urethral valve. *Courtesy Drs. Long, Shukla, and Srinivasan*
Video 33.2 Repair of Y-configuration urethral duplication. *Courtesy Drs. Srinivasan and Bowen*
Chapter 37 Lower Urinary Tract Reconstruction in Children
Video 37.1 Implanting catheterizable channel into

bladder. *Courtesy John C. Thomas and Mark C. Adams*
Video 37.2 Catheterizable channel (Monti). *Courtesy John C. Thomas and Mark C. Adams*
Video 37.3 Laparoscopic-assisted MACE in children. *Courtesy Steven G. Docimo*

SECTION E Genitalia

Chapter 45 Hypospadias

Video 45.1 First stage proximal hypospadias repair with dermal patch graft correction of ventral penile curvature
Video 45.2 First stage hypospadias repair with dermal graft correction of ventral chordee and free inner preputial graft glansplasty
Video 45.3 Reverse pedicle barrier flap for circumcised boys with hypospadias
Video 45.4 Belman flap
Video 45.5 Meatal advancement glansplasty (MAGPI)
Video 45.6 M inverted V plasty (MIV)
Video 45.7 Thiersch-Duplay
Video 45.8 Thiersch-Duplay without meatoplasty
Video 45.9 Duckett tube
Video 45.10 Second stage urethroplasty with tunica

        - **vaginalis coverage**
        - **Video 45.11 First stage repair of perineal hypospadias with penoscrotal transposition**
        - **Video 45.12 Buccal graft interposition for complex hypospadias reconstruction**
        - **Video 45.13 Closure of urethrocutaneous fistula**
        - **Video 45.14 Repeat Thiersch-Duplay for coronal urethrocutaneous fistula**
        - **Video 45.15 Buccal mucosa graft inlay**
        - **Video 45.16 Urethral diverticulum closure**
    - Chapter 46 **Etiology, Diagnosis, and Management of Undescended Testis**
        - **Video 46.1 Inguinal orchidopexy**
        - **Video 46.2 Transscrotal orchidopexy**
        - **Video 46.3 Laparoscopic orchiopexy**
- PART VI **Reproductive and Sexual Function**
    - Chapter 67 **Surgical Management of Male Infertility**
        - **Video 67.1 General preparation for vasovasostomy.** *Courtesy Marc Goldstein*
        - **Video 67.2 Surgical techniques for vasovasostomy.** *Courtesy Marc Goldstein*
        - **Video 67.3 Microsurgical**

vasovasostomy (microdot suture placements). *Courtesy Marc Goldstein*

Video 67.4 General preparation for vasoepididymostomy. *Courtesy Marc Goldstein*

Video 67.5 Preparation for anastomosis in vasoepididymostomy. *Courtesy Marc Goldstein*

Video 67.6 Varicocelectomy. *Courtesy Marc Goldstein*

Video 67.7 Vasography. *Courtesy Marc Goldstein*

Video 67.8 Vasography and transurethral resection of the ejaculatory ducts. *Courtesy Marc Goldstein*

Chapter 72 Surgery for Erectile Dysfunction

Video 72.1 Implantation of AMS 700 LGX inflatable penile prosthesis. *Courtesy Drogo K. Montague*

Video 72.2 Prosthetic surgery for erectile dysfunction. *Courtesy Drogo K. Montague*

Chapter 73 Diagnosis and Management of Peyronie's Disease

Video 73.1 Reconstruction for Peyronie's disease: incision and grafting. *Courtesy Gerald H. Jordan*

PART VII **Male Genitalia**

- Chapter 75 **Surgical, Radiographic, and Endoscopic Anatomy of the Retroperitoneum**
  - **Video 75.1 Interaortal caval region.** *Courtesy James Kyle Anderson*
  - **Video 75.2 Right retroperitoneum.** *Courtesy James Kyle Anderson*
  - **Video 75.3 Left lumbar vein.** *Courtesy James Kyle Anderson*
  - **Video 75.4 Lumbar artery.** *Courtesy James Kyle Anderson*
- Chapter 77 **Surgery of Testicular Tumors**
  - **Video 77.1 Retroperitoneal lymph node dissection: the split and roll technique.** *Courtesy Kevin R. Rice, K. Clint Cary, Timothy A. Masterson, and Richard S. Foster*
- Chapter 78 **Laparoscopic and Robotic-Assisted Retroperitoneal Lymphadenectomy for Testicular Tumors**
  - **Video 78.1 Laparoscopic retroperitoneal lymph node dissection: patient 1.** *Courtesy Frederico R. Romero, Soroush Rais-Bahrami, and Louis R.*

Kavoussi

- Chapter 79 **Tumors of the Penis**
    - **Video 79.1 Partial penectomy.** *Courtesy Curtis A. Pettaway, Juanita M. Crook, Lance C. Pagliaro*
    - **Video 79.2 Low dose rate brachytherapy.** *Courtesy Curtis A. Pettaway, Juanita M. Crook, Lance C. Pagliaro*
- Chapter 80 **Tumors of the Urethra**
    - **Video 80.1 Male total urethrectomy.** *Courtesy Hadley M. Wood and Kenneth W. Angermeier*

PART VIII **Renal Physiology and Pathophysiology**

- Chapter 84 **Surgical, Radiologic, and Endoscopic Anatomy of the Kidney and Ureter**
    - **Video 84.1 Left gonadal vein.** *Courtesy James Kyle Anderson*
    - **Video 84.2 Left renal hilum.** *Courtesy James Kyle Anderson*
    - **Video 84.3 Right kidney before dissection.** *Courtesy James Kyle Anderson*
    - **Video 84.4 Left lower pole crossing vessel.** *Courtesy James Kyle Anderson*
    - **Video 84.5 Digital nephroscopy: the next step.**

Reproduced with permission from Andonian S, Okeke Z, Anijar M, et al. Digital nephroscopy: the next step. J Endourol Part B Videourology *24, 2010a.*

Video 84.6 Digial ureteroscopy: the next step. *Reproduced with permission from Andonian S, Okeke Z, Smith AD: Digital ureteroscopy: the next step.* J Endourol Part B Videourology *24, 2010b.*

Chapter 88 **Urological Complications of Renal Transplantation**

Video 88.1 Technique of laparoscopic live donor nephrectomy. *Courtesy Michael Joseph Conlin and John Maynard Barry*

Video 88.2 Laparoscopic live donor nephrectomy. *Louis R. Kavoussi*

PART IX **Upper Urinary Tract Obstruction and Trauma**

Chapter 89 **Management of Upper Urinary Tract Obstruction**

Video 89.1 Laparoscopic pyeloplasty. *Courtesy Frederico R. Romero, Soroush Rais-Bahrami, and Louis R. Kavoussi*

Video 89.2 Robotic-assisted laparoscopic pyeloplasty.

Courtesy Sutchin R. Patel and Sean P. Hedican

PART X **Urinary Lithiasis and Endourology**

- Chapter 94 **Surgical Management for Upper Urinary Tract Calculi**
  - **Video 94.1 Blast wave lithotripsy.** *Courtesy Brian R. Matlaga and Amy E. Krambeck*
  - **Video 94.2 Shock wave lithotripsy.** *Courtesy Brian R. Matlaga and Amy E. Krambeck*
  - **Video 94.3 Shockpulse lithotripsy.** *Courtesy Brian R. Matlaga and Amy E. Krambeck*
  - **Video 94.4 Venturi effect.** *Courtesy Brian R. Matlaga and Amy E. Krambeck*

PART XI **Neoplasms of the Upper Urinary Tract**

- Chapter 101 **Open Surgery of the Kidney**
  - **Video 101.1 Patient case study.** *Courtesy Aria F. Olumi and Michael L. Blute*
  - **Video 101.2 Global ischemia.** *Courtesy Aria F. Olumi and Michael L. Blute*
  - **Video 101.3 Regional ischemia.** *Courtesy Aria F. Olumi and Michael L. Blute*
  - **Video 101.4 Vena cava tumor thrombectomy.** *Courtesy Aria*

F. Olumi and Michael L. Blute

Chapter 102 **Laparoscopic and Robotic Surgery of the Kidney**

- **Video 102.1 Laparoscopic partial nephrectomy.** *Courtesy Frederico R. Romero, Soroush Rais-Bahrami, and Louis R. Kavoussi*

Chapter 103 **Nonsurgical Focal Therapy for Renal Tumors**

- **Video 103.1 Percutaneous renal cryoablation.** *Courtesy Arvin K. George, Zhamshid Okhunov, Soroush Rais-Bahrami, Sylvia Montag, Igor Lobko, and Louis R. Kavoussi*

PART XII **The Adrenals**

Chapter 105 **Surgical and Radiographic Anatomy of the Adrenals**

- **Video 105.1 Left adrenal vein.** *Courtesy James Kyle Anderson*
- **Video 105.2 Right adrenal vein.** *Courtesy James Kyle Anderson*

Chapter 107 **Surgery of the Adrenal Glands**

- **Video 107.1 Laparoscopic adrenalectomy.** *Courtesy Frederico R. Romero, Soroush Rais-Bahrami, and Louis R. Kavoussi*

PART XIII **Urine Transport, Storage, and Emptying**

Chapter 110 Physiology and Pharmacology of the Bladder and Urethra

- **Video 110.1 Urothelial cells responding to carbachol, a nonspecific muscarinic agonist.** *Courtesy Toby C. Chai, University of Maryland School of Medicine*
- **Video 110.2 Actin-myosin cross bridge cycling.** *Courtesy Toby C. Chai, Yale School of Medicine*
- **Video 110.3 Digital calcium fluorescent microscopy of a muscle myocyte contraction.** *Courtesy George J. Christ, David Burmeister, and Josh Tan, Wake Forest University School of Medicine*
- **Video 110.4 Calcium spark development in myocyte.** *Courtesy Toby C. Chai, Yale School of Medicine*

Chapter 112 Evaluation and Management of Women With Urinary Incontinence and Pelvic Prolapse

- **Video 112.1 Discussion of normal lower urinary tract function.** *Courtesy Roger Dmochowski*
- **Video 112.2 Live interview of a patient with pelvic floor disorders.** *Courtesy Roger*

Dmochowski

Video 112.3 Case study of a patient with mixed urinary incontinence. *Courtesy Roger Dmochowski*

Video 112.4 Examination of a patient with significant anterior vaginal wall prolapse. *Courtesy Roger Dmochowski*

Video 112.5 Case study of a patient with symptomatic prolapse and incontinence. *Courtesy Roger Dmochowski*

Video 112.6 Demonstration of “eyeball” filling study in a patient with incontinence and prolapse. *Courtesy Roger Dmochowski*

Video 112.7 Q-tip test in a patient with minimal urethral mobility. *Courtesy Roger Dmochowski*

Chapter 114 **Urodynamic and Video-Urodynamic Evaluation of the Lower Urinary Tract**

Video 114.1 Overview of urodynamic studies in female pelvic floor dysfunction. *Courtesy Alan J. Wein, Louis R. Kavoussi, Alan W. Partin, and Craig A. Peters*

Chapter 115 **Urinary Incontinence and**

Pelvic Prolapse: Epidemiology and Pathophysiology
    - **Video 115.1 The Pelvic Organ Prolapse Quantification (POPQ) system.** *Courtesy Jennifer T. Anger and Gary E. Lemack*
- Chapter 125 **Slings: Autologous, Biologic, Synthetic, and Midurethral**
    - **Video 125.1 Distal urethral polypropylene sling.** *Courtesy Shlomo Raz and Larissa Rodriguez*
    - **Video 125.2 Rectus fascia pubovaginal sling procedure.** *Courtesy Alan J. Wein, Louis R. Kavoussi, Alan W. Partin, and Craig A. Peters*
    - **Video 125.3 Top-down retropubic mid-urethral sling: SPARC.** *Courtesy Alan J. Wein, Louis R. Kavoussi, Alan W. Partin, and Craig A. Peters*
    - **Video 125.4 Outside-in transobturator mid-urethral sling: MONARC.** *Courtesy Alan J. Wein, Louis R. Kavoussi, Alan W. Partin, and Craig A. Peters*
    - **Video 125.5 MiniArc single-incision sling system.** *Courtesy Alan J. Wein, Louis*

R. Kavoussi, Alan W. Partin, and Craig A. Peters

Chapter 129 Urinary Tract Fistulae

- **Video 129.1 Robotic-assisted laparoscopic repair of complex vesicovaginal fistula in a patient with failed open surgical and vaginal repair.** *Courtesy Ashok K. Hemal and Gopal H. Badlani*
- **Video 129.2 Martius flap.** *Courtesy Shlomo Raz and Larissa Rodriguez*
- **Video 129.3 Transvaginal repair of a vesicovaginal fistula using a peritoneal flap.** *Courtesy Shlomo Raz and Larissa Rodriguez*
- **Video 129.4 Transvaginal bladder neck closure with posterior urethral flap.** *Courtesy Brett D. Lebed, J. Nathaniel Hamilton, and Eric S. Rovner*

Chapter 131 Surgical Procedures for Sphincteric Incontinence in the Male

- **Video 131.1 Surgical treatment of the male sphincteric urinary incontinence: the male perineal sling and artificial urinary sphincter.** *Courtesy David R. Staskin and Craig V. Comitor*

- **Video 131.2 Male sling.** *Courtesy Hunter Wessells*

PART XIV **Benign and Malignant Bladder Disorders**

- Chapter 133 **Genital and Lower Urinary Tract Trauma**
  - **Video 133.1 Technique demonstrating protection of phallus during removal of penile strangulation device.** *Courtesy Allen F. Morey and Jay Simhan*
- Chapter 134 **Special Urologic Considerations in Transgender Individuals**
  - **Video 134.1 Creation of the neo-urethra**
  - **Video 134.2 Creation of the neoscrotum**
  - **Video 134.3 Procedure for implantation of erectile device**
- Chapter 135 **Tumors of the Bladder**
  - **Video 135.1 Patient case studies using blue light cystoscopy (BLC).** *Courtesy Max Kates and Trinity J. Bivalacqua*
- Chapter 136 **Management Strategies for Non–Muscle-Invasive Bladder Cancer (Ta, T1, and CIS)**
  - **Video 136.1 Demonstration of the technique of en bloc resection of bladder tumor**

completed cystoscopically with a resectoscope and bipolar cutting loop. *Courtesy Giulia Lane*

Chapter 140 **Cutaneous Continent Urinary Diversion**

Video 140.1 Stapled right colon reservoir with appendiceal stoma. *Courtesy Mitchell C. Benson*

Chapter 141 **Orthotopic Urinary Diversion**

Video 141.1 T-pouch ileal neobladder. *Courtesy Eila C. Skinner, Donald G. Skinner, and Hugh B. Perkin*

Video 141.2 The modified Studer ileal neobladder. *Courtesy Siamak Daneshmand*

PART XV **The Prostate**

Chapter 146 **Minimally Invasive and Endoscopic Management of Benign Prostatic Hyperplasia**

Video 146.1 Holmium laser enucleation of the prostate (HoLEP). *Courtesy Mitra R. de Cógáin and Amy E. Krambeck*

Chapter 147 **Simple Prostatectomy: Open and Robot-Assisted Laparoscopic Approaches**

Video 147.1 Robot-assisted laparoscopic simple prostatectomy. *Courtesy*

Misop Han

Chapter 151 **Prostate Biopsy: Techniques and Imaging**

Part II Basics of Urologic Surgery
Part III Pediatric Urology

PART I

Clinical Decision Making

OUTLINE

1 Evaluation of the Urologic Patient History and Physical Examination

2 Evaluation of the Urologic Patient Testing and Imaging

3 Urinary Tract Imaging Basic Principles of CT, MRI, and Plain Film Imaging

4 Urinary Tract Imaging Basic Principles of Urologic Ultrasonography

5 Urinary Tract Imaging Basic Principles of Nuclear Medicine

6 Assessment of Urologic and Surgical Outcomes

7 Ethics and Informed Consent

Evaluation of the Urologic Patient

History and Physical Examination

Sammy E. Elsamra MD

The evaluation of a patient must always begin with a thorough and appropriate history and physical examination. By using an organized system of information accrual, the urologist can gather information pertinent to the cause (or contributing factors) of a disease and obtain information salient to its treatment. To do so reliably for every patient, a reproducible system of history and physical examination has been developed and is taught routinely at all medical schools, usually in the preclinical years. Laboratory and radiologic examinations should be performed based on the findings of history and physical examination to narrow the differential diagnosis and arrive at an accurate diagnosis. A proper history and physical examination also allow for the development of rapport and trust between physician and patient, which can prove invaluable in counseling patients on subsequent diagnostic and treatment decisions.

Often health care providers are tempted to solicit information from the medical record or previously obtained labs and images. Although reviewing such data is critical, the urologist must be careful not to fall into the trap of relying too heavily on this data without input from the patient; chart lore, aberrant labs, and “incidentalomas” encountered may steer subsequent diagnostic evaluations and treatment away from the true illness. In our practice we have encountered patients with hematuria whose penile tumor is identified on physical examination.

This chapter provides a concise yet comprehensive discussion pertinent to the urologist of taking a history and performing a physical exam.

History

Overview

The medical history is the foundation for the evaluation and management of urologic patients. Often a well-obtained history provides the diagnosis or at least properly directs the health care provider to arrive at the correct diagnosis. Establishing several parameters helps to optimize the encounter. First, the environment should be warm, comforting, and nonthreatening for the patient. If the provider has any control over the waiting room or intake process, these should be made as easy as possible for the patient to navigate; this avoids agitating the patient before beginning the provider-patient encounter. Difficulties with parking or with front office staff may upset a patient before meeting the provider. The patient is directed to the examination room; ideally the physician reviews the patient's vitals and prior records before entering this room. A physician's knock before entering the room and an introduction upon entering help to put the patient at ease. If possible, the room should be properly set up for ideal provider-patient positioning, face to face, without any barriers (especially a computer). If a computer is used during the session, the provider ideally should still face the patient and place the computer off to the side so that the patient does not feel secondary to the computer. Although such factors may seem insignificant, it is clear that nonverbal communication is most responsible for communicating emotions, attitudes, and affect (Silverman and Kinnersley, 2010). In fact, studies have shown that patients may reveal more or less information based on level of eye contact and physician posture during the encounter (Byrne and Heath, 1980).

In addition to establishing an optimal setup, the physician must appreciate the patients' level of comprehension. Whether this entails assessing their ability to communicate in interview language or their ability to comprehend complex matters, the physician must assess level of comprehension by reading nonverbal cues or asking patients to summarize the discussion. Further, the patient encounter may be enhanced by the presence of a family member or friend. Often patients may not be as aware of pertinent historical details that family members may be able to supply. Further, when patients are given difficult news (e.g., cancer diagnosis, recommendation to remove an organ), they often cease to listen effectively (Kessels, 2003). The family member or friend may be able to focus, take notes, and relay the information provided by the physician to the patient at a time when the shock of the unfortunate news has passed. Even without shocking news, some instructions or discussions regarding risks, benefits, and alternative treatments may be lengthy and complex, and a second person in audience helps reinforce that information.

A complete history includes the chief complaint, history of present illness (HPI), past medical and surgical history, history of allergic reactions, social and family history, and a review of systems. The surgeon should obtain this information in a direct fashion. Patients should be given the opportunity to express any concerns or pertinent history, but often the physician must focus the conversation to obtain the information necessary to make a diagnosis and avoid pitfalls in treatment.

Chief Complaint

Often patients can identify an issue as urologic. Therefore they may present directly to the urologist with a particular problem or chief complaint. The chief complaint is the reason why the patient is seeking urologic care; this should be the urologist's focus. Although other urologic issues may be identified, the urologist's goal should be to target the chief complaint to allay the patient's immediate concerns. For example, the patient presents with urinary frequency is identified to have a renal mass; addressing the renal mass but not addressing the urinary frequency may be seen as ineffective care by the patient. With a clear chief complaint, the urologist should begin to think of a differential diagnosis and then narrow the possibilities with the HPI.

History of Present Illness

The HPI incorporates questions to identify the timing, severity, nature, and factors that may exacerbate or relieve the issue identified in the chief complaint. For an efficient HPI, the urologist creates a differential diagnosis based on the chief complaint and then asks questions to help support or oppose a diagnosis on the differential list.

The following sections review a variety of typical chief complaints to highlight considerations for the HPI.

Pain

Pain can often be a chief complaint or a factor elicited while obtaining the HPI. The astute clinician must be able to identify the location of pain and characterize its nature; this information will help pinpoint the cause or, at a minimum, direct further examination and testing. It is prudent to assess the onset and duration and to ascertain if this pain episode has occurred previously. In our practice, we have encountered patients with initial obstructive ureteral stones with renal colic (and little experience with kidney stones) who often inappropriately attribute the pain to some gastrointestinal or musculoskeletal cause. However, the same patient will then become very familiar with the nature of this obstructing stone pain and associated symptoms and readily identify the presence of an obstructing stone upon recurrence of such pain.

Often patients can localize pain. While gathering the HPI, the physician should direct patients to point to the site of maximal pain with one finger. An important distinction is made between pain and tenderness. Later in the physical examination, the physician must assess if there is tenderness (pain with palpation) in that location or elsewhere. Although pain and tenderness often overlap in location, a site of pain without tenderness may be the result of referred pain. An example is testicular pain without testicular tenderness; the pain in the testicle can often be referred pain from an obstructing ipsilateral ureteral stone.

The severity of the pain should be assessed and documented. Pain severity can be characterized as mild, moderate, or severe or based on a 1-to-10 scale. This commonly used scale as described by Wong and Baker in 1988 uses face illustrations with increasing appearance of distress/discomfort along a 10-point scale (Wong and Baker, 1988). This scale helps document the severity of pain before and after intervention.

Pain can be due to distention from obstruction or inflammation within the parenchyma of a genitourinary (GU) organ. Obstructive pain results in distention of a hollow organ (or hollow portion) of the organ resulting from some obstruction (e.g., ureteral stone for renal pelvis or ureter and bladder outlet obstruction for bladder). In the kidney, for example, this can result in colicky-type pain, typified by a patient with intermittent pain for which the patient is always moving to seek a position of comfort. This contrasts with parenchymal pain, such as pyelonephritis, which is typified by constant pain and is the result of inflammation, infection, or subcapsular bleeding causing distention within the parenchyma of the GU organ. This pain is typified by a patient who lays still, seeking not to exacerbate the pain with motion.

An understanding of nervous system anatomy can facilitate comprehension of some of the associated signs or symptoms seen with GU pain. For example, the celiac plexus is responsible for the visceral innervation of the foregut and the kidneys. Therefore irritation of the kidneys can result in paroxysmal nausea and vomiting. In addition, irritation of the ureter may result in referred pain to the ipsilateral testicle in men or labium in women because of the common nerve supply to these areas. Rarely pain can be due to tumor infiltration of the periparenchymal nerves. However, often this is a late sign and a manifestation of advanced disease.

Pain of an acute nature often is due to a clear cause. Obstruction or inflammation of an organ causes the release of prostaglandins or chemokines that result in noxious stimulation of nerves. These signals are transmitted from the peripheral nervous system to the central nervous system and perceived as pain. This mechanism is complex, and signals can be amplified or diminished en route to the central nervous system (Urban and Gebhart, 1999). Medications and techniques used to treat pain either target the noxious chemoneural agent (e.g., nonsteroidal anti-inflammatory drugs [NSAIDs] inhibit the production of prostaglandins) or interfere with opioid or other receptors in the brain. Chronic pain can be much more complex with possible signal imprinting within the pain, resulting in the sensation of pain without noxious stimuli, such as in chronic pelvic pain disorder or fibromyalgia (Woolf, 2011). When no clear urologic cause is identified after an appropriately thorough evaluation, referral to a pain specialist should be considered.

Renal Pain.

Renal pain is typified by location in the ipsilateral costovertebral angle just lateral to the vertebral spine and inferior to the 12th rib. It can be due to obstruction of the ipsilateral collecting system (causing colicky-type pain) or inflammation or infection of the renal parenchyma (causing flank pain and costovertebral angle tenderness). The pain may radiate anteriorly across the flank and toward the abdominal midline or down toward the ipsilateral scrotum or labium. Pain in this location also can be from gastrointestinal or musculoskeletal sources. Intraperitoneal causes of pain often are typified by a relationship to food ingestion or irregularity with bowel function. Further, peritoneal irritation causes peritoneal signs on abdominal exam (exquisite tenderness to any abdominal motion). Further tenderness would be most pronounced anteriorly (such as the Murphy sign for acute cholecystitis) as opposed to costovertebral angle tenderness (CVAT). Intraperitoneal pathology may cause ipsilateral shoulder pain from diaphragmatic irritation via the phrenic nerve; renal pain typically does not.

Ureteral Pain.

Ureteral pain typically is due to ureteral obstruction, is acute in onset, and is located to the ipsilateral lower quadrant. The acute distention of the ureter and hyperperistalsis result in pain as prostaglandins accumulate, causing ureteral spasm, which in turn causes increased lactic acid production, which in turn irritates type A and C nerve fibers in the ureteral wall. These nerve fibers conduct signal toward T11-L1 dorsal root ganglia, and this irritation is perceived as pain. Ureteral obstruction of a gradual or partial nature may not cause pain. The point of ureteral obstruction may result in referred pain to the ipsilateral scrotum or penis. Obstruction at the ureterovesical junction also may result in irritative voiding symptoms (with noncommiserate urinary volume).

Vesicle Pain.

If the bladder is inflamed (as in cystitis) or distended because of obstruction (as in acute urinary retention), suprapubic pain may be present. Inflammation of the bladder caused by infection or interstitial cystitis is worst when the bladder is distended, so patients may report improvement in suprapubic pain with voiding. Patients also may describe strangury, a sharp and stabbing pain at the end of urination (presumably resulting from final contraction of the inflamed detrusor). In sensate bladders, acute urinary retention can be easily identified from the history: profound desire to urinate without ability to do so. However, in patients with flaccid atonic bladders, large volumes of urine can be retained without any symptoms.

Prostatic Pain.

Inflammation of the prostate, prostatitis, can result in pain that is located deep within the pelvis. It can be difficult to localize and sometimes is confused with rectal pain. Irritative voiding symptoms (urinary frequency, urgency, and dysuria) are often associated with irritation of the prostate.

Penile Pain.

The differential for penile pain includes paraphimosis, ulcerative penile lesions (e.g., cancer or herpes), or referred pain from cystitis/prostatitis in the flaccid penis. In the rigid penis, Peyronie disease or priapism may be the cause.

Scrotal Pain.

Pain within the scrotum may be due to irritation of the scrotal skin, such as an inflamed pustule from an ingrown hair or from the testicles and cord within. Epididymitis and orchitis are typified by testicular pain that may be relieved by maneuvers that elevate or support the testis. Torsion of the testicle or its appendages result in acute vascular congestion and pain (and in the case of testicular torsion is a surgical emergency). Varicoceles may result in a dull ache particularly toward the end of the day from accumulated vascular congestion. Again, because of common embryologic origins and therefore neurologic pathways, pain within the kidney or ureter may be referred to the ipsilateral scrotum.

Narcotic Considerations.

Currently, the United States is dealing with an alarmingly high rate of opioid abuse. On October 6, 2017, the president of the United States declared a national public health emergency to help curtail opioid abuse and diversion (https://cnn.com, 2018). Diversion, or the exchange of prescription controlled substances for money or illicit substances, has placed physicians in a precarious position. Physicians and pharmaceutical companies have been implicated in contributing to this epidemic by falsely promoting synthetic narcotics as “safer” than natural narcotics or by being complacent in prescribing narcotic pain medication. To this end, many recent studies have sought to identify and quantify the severity of pain of certain urologic diseases and surgery and to assess the utility of nonopioid analgesics for patients. In general, urologic conditions causing pain should be addressed promptly to minimize the need for narcotic use. Non-narcotic analgesia (NSAIDs, physical therapy, neuromodulation, acupuncture) should be used whenever possible to minimize narcotic use. Patients with pain with no identifiable urologic cause should not be offered narcotics and rather should be referred to their primary care physician and/or pain management specialists.

Urologists also should be cognizant of signs for narcotic-seeking behavior and narcotic abuse. All medical students are taught the side effects of narcotics. Besides euphoria, patients often are afflicted with constipation/ileus, dizziness, nausea, vomiting, tolerance, physical dependence, and respiratory depression (Benyamin et al., 2008). Patients seeking narcotics may come from unusual locations, exhibit inconsistent behavior (facile walking in hallway but difficulty walking in examination room), demonstrate noncompliant follow-up, demonstrate disinterest in non-narcotic analgesia, or request specific narcotics by brand name (Pretorius and Zurick, 2008). Clearly, it is important to obtain a thorough HPI seeking any discrepancies and/or rehearsed answers to avoid contributing to this epidemic.

Hematuria

Hematuria, or the presence of blood in the urine, is a concerning urologic sign in adults and must be evaluated because it may signal the presence of a urologic cancer in up to 25% of patients with this complaint. Hematuria comes in two varieties: gross and microscopic. Gross hematuria is often alarming to the patient, whereas microscopic hematuria is unnoticed by the patient until it is detected by a urinalysis. Critical to the HPI for hematuria are the age, presence of irritative voiding symptoms, smoking history, and industrial chemical exposure history because these are risk factors for detecting cancer. Further, exposure to alkylating chemotherapy, analgesic abuse history, or chronic foreign objects in the urinary tract should increase suspicion for GU malignancy.

After excluding urinary tract infection (particularly in young women), history of nephrologic pathology, trauma, or recent urologic manipulation, the physician should give the patient a full urologic evaluation for hematuria according to American Urological Association (AUA) guidelines. Interestingly, several studies demonstrate age as a risk factor for GU malignancy detection on evaluation for hematuria; however, children with GU malignancies have been described (Commander et al., 2017). In fact, the most common cause of gross hematuria in a patient older than 50 years of age is bladder cancer.

Hematuria must be differentiated from pseudohematuria, whereby the urine may appear red because of dehydration or certain medicines or foods (Hubbard and Amin, 1977). The way to differentiate hematuria from pseudohematuria is to obtain a clean midstream urine sample and assess for red blood cells (RBCs) on the microscopic analysis. The urine dipstick alone is not sufficient for determining the presence of true hematuria because it may signal the presence of “hematuria” when no RBCs are present but rather other solutes that discolor the urine. In fact, proceeding with a full hematuria evaluation for dipstick pseudohematuria is associated with unnecessary cost and low yield for detecting malignancy (Rao et al., 2010).

When encountering a patient with hematuria, the physician must ascertain duration of onset and several associated factors. Patients should be queried as to which portion of the urinary stream contains urine: the initial part of the stream, the entire stream, or the terminal portion of the urinary stream. Initial stream hematuria often signifies mild bleeding from a prostatic or urethral source, and terminal hematuria often signifies bladder neck irritation that expresses hematuria upon contraction of the bladder neck at the end of urination. Other helpful clues include any associated pain and clots associated with the hematuria.

Hematuria usually is painless, but pain can occur when clots obstruct the upper urinary tract (see Renal Pain earlier) or cause urinary retention. The shape of clots can help elucidate their origin: clots formed in the upper tract often have a vermiform shape, whereas cuboid clots are likely produced in the bladder.

Lower Urinary Tract Symptoms

Patients often come to the urologist with lower urinary tract symptoms (LUTS). LUTS are symptoms associated with the urinary bladder and its outlet. Such symptoms can be due to any combination of obstructive or irritative causes. Causes of lower urinary tract obstruction include benign prostatic hyperplasia (BPH), obstructive prostate cancer, urethral stricture disease, dysfunctional voiding, detrusor-external sphincter dyssynergia, severe phimosis, and severe meatal stenosis. In short, anything that can obstruct or narrow the caliber of the urethra can cause obstructive LUTS. Although a complete obstruction results in urinary retention, a partial obstruction results in obstructive LUTS (oLUTS); namely sensation of incomplete urinary emptying, urinary frequency (more frequently than every 2 hours), intermittency (intermittent flow of urinary steam), weak urinary stream, and urinary straining (requiring Valsalva maneuver to aid in voiding). In patients with weak detrusor muscle activity, even a minimally obstructive outlet can result in oLUTS or even urinary retention. Therefore it is important to consider causes for hypocontractile or acontractile bladders when evaluating a patient with oLUTS. It is also important to remark that bladder outlet obstruction may result in varying levels of urinary retention. Some patients may urinate their bladder volume incompletely and therefore have an elevated residual volume, whereas other patients may not be able to urinate at all and be in outright urinary retention. Often the progression of obstruction, for instance in BPH, is slow, and therefore changes in urinary stream may not be easily acknowledged by the patient. Further, because of such acclimation and possibly peripheral neuropathy, many patients may not appreciate the level of obstruction they have (which would be evidenced by objective measures of weak urinary stream and elevated residual stream). Oddly enough, chronic bladder outlet obstruction can result in detrusor irritability with irritative voiding symptoms.

Irritative LUTS (iLUTS) include urinary frequency, urgency, and dysuria. Causes of irritative voiding symptoms, other than chronic bladder outlet obstruction, include overactive bladder, cystitis, prostatitis, bladder stones, or bladder cancer. Urinary frequency entails urinary voiding of more than five or six times per day. It is normal to void up to twice per night, but nocturia of more than twice per night merits urologic evaluation. A bladder diary is helpful in determining if the urinary frequency may be due to incomplete bladder emptying, overactive bladder, or polyuria (increased urinary output). Polyuria may be due to polydipsia (behavioral or otherwise), diabetes mellitus, diabetes insipidus, or other reasons.

The rationale for the use of a bladder diary is located elsewhere in the text. A bladder diary, briefly, is a tabulation of all fluid ingested and all urine produced by a patient with associated times and volumes. Preferably patients note sensations of urgency or urinary incontinence on this tabulation. Typically a bladder diary is kept for 48 hours. The bladder diary can help provide insight into the functional capacity of a bladder, which should be around 300 to 400 mL in a normal adult and can help quantify the severity of nocturia. Daytime frequency without nocturia may be due to psychogenic reasons (e.g., anxiety). Nocturia without daytime frequency can be due to increased nighttime polyuria. This can be due to excessive fluid intake before bed (which can be easily elucidated from the bladder diary) or increased intravascular volume resulting from the return of fluid from lower extremity peripheral edema upon elevation of legs for recumbency of sleep. Further, as patients age, renal concentrating ability diminishes, which may result in increased urine production at night when renal blood flow is increased (Weiss and Blaivas, 2000).

Urinary urgency indicates difficulty in postponing urination. Although this sensation may be normal if a patient has held his or her urine for a prolonged period, it should not occur otherwise. Dysuria is painful urination and is typically due to inflammation within the bladder. The pain is often felt along the urethra or referred to the urethral meatus. It is important to highlight that irritative voiding symptoms, particularly in patients older than 50 years and with smoking history, can be the only sign of an occult bladder cancer, particularly carcinoma in situ; therefore a low threshold for cystoscopy should exist for patients presenting with iLUTS.

Urinary hesitancy refers to delay in the start of urination. Typically, micturition occurs a second after the urinary sphincter relaxes. However, in men with bladder outlet obstruction, there may a prolongation of this delay. Postvoid dribbling refers to the loss of a few drops of urine at the end of urination. This is often an early symptom of urethral obstruction related to BPH and is due to the escape of urine into the urethra that is not “milked back” into the bladder at the end of urination (Stephenson and Farrar, 1977). Men may describe shaking the penis to evacuate such residual urine and prevent wetting their clothes. Straining refers to the use of Valsalva maneuver or manual abdominal pressure (i.e., Crede voiding) to help push the urine out and can be easily performed by the patient.

The AUA symptom score was introduced in 1992 and quantifies the presence of many of the symptoms mentioned above onto a scale. The questionnaire assesses whether incomplete emptying, urinary frequency, intermittency, urgency, weak stream, straining, and nocturia were present over the prior month. Answer choices range from 0 to 5 for each question depending on prevalence (not at all, less than 1 time in 5, less than half the time, about half the time, more than half the time, and almost always). Nocturia, however, is not a prevalence over the prior month but rather the typical number of times the patient arises from sleep to urinate (0 to 5; 5 representing 5 times or more per night). The sum of the values indicates the severity of symptoms (0 to 7 is mild, 8 to 19 is moderate, 20 to 35 is severe). The International Prostate Symptom Score (IPSS) is the AUA symptom score with the addition of a quality-of-life score (Barry et al., 1992) (Table 1.1). Although this tool has many limitations (nonspecific, requires sixth-grade reading level, may not be answered by those with neurologic conditions) is very useful in quantifying and standardizing urinary symptoms to help compare patient encounters after intervention (MacDiarmid et al., 1998).

TABLE 1.1

International Prostate Symptom Score

SYMPTOM	NOT AT ALL	<1 TIME IN 5	LESS THAN HALF THE TIME	ABOUT HALF THE TIME	MORE THAN HALF THE TIME
1. INCOMPLETE EMPTYING					

Over the past month, how often have you had a sensation of not emptying your bladder completely after you finished urinating?	0	1	2	3	4
2. FREQUENCY					
Over the past month, how often have you had to urinate again less than 2 hours after you finished urinating?	0	1	2	3	4
3. INTERMITTENCY					
Over the past month, how often have you found you stopped and started again several times when you urinated?	0	1	2	3	4
4. URGENCY					
Over the past month, how often have you found it difficult to postpone urination?	0	1	2	3	4
5. WEAK STREAM					
Over the past month, how	0	1	2	3	4

often have you had a weak urinary stream?					
6. STRAINING					
Over the past month, how often have you had to push or strain to begin urination?	0	1	2	3	4
	NONE	1 TIME	2 TIMES	3 TIMES	4 TIMES
7. NOCTURIA					
Over the past month, how many times did you most typically get up to urinate from the time you went to bed at night until the time you got up in the morning?	0	1	2	3	4
TOTAL INTERNATIONAL PROSTATE SYMPTOM SCORE					
QUALITY OF LIFE DUE TO URINARY SYMPTOMS	DELIGHTED	PLEASED	MOSTLY SATISFIED	MIXED—ABOUT EQUALLY SATISFIED AND DISSATISFIED	MOSTLY DISSATISFIED
If you were to spend the rest of your life with your urinary condition just the way it is now, how would you	0	1	2	3	4

feel about that?

In Cockett ATK, Khoury S, Aso Y, et al., eds: *Proceedings of the Second International Consultation on Benign Prostatic Hyperplasia (BPH); 27-30 June 1993,* Paris, Channel Island, 1994, Jersey: Scientific Communication International, pp 553–555.

Urinary Incontinence.

Urinary incontinence is the involuntary passage of urine. The reasons for urinary incontinence are many and can be due to several pathologies. In general when the pressure within the bladder is greater than the resistance provided by the urethra, or when it is bypassed, urinary incontinence may occur. A thorough differential diagnosis can help the urologist direct the questioning to arrive at the likely diagnosis. It is helpful to understand the eight categories of urinary incontinence.

Stress Incontinence.

Stress urinary incontinence refers to the involuntary passage of urine with any activity that increases intra-abdominal pressure. This is typically indicative of weakness in the urinary sphincter and can be seen in multiparous women, postmenopausal women, and men who have had radical prostatectomy or another procedure affecting the outlet (aggressive transurethral resection of the prostate [TURP]). Patients complain of such loss of urine with Valsalva maneuvers, typically coughing, sneezing, laughing, or heavy lifting. Generally, the treatment for stress urinary incontinence involves exercises or surgeries that increase the resistance of the urinary outlet (e.g., Kegel exercises, urethral sling, artificial urinary sphincters, urethral bulking).

Urge Incontinence.

Urinary urgency, described previously, may be due to a myriad of reasons. This occurs when a patient experiences involuntary passage of urine coincident with sensation of urinary urgency. This is often a symptom of severe overactive bladder, cystitis, or neurogenic bladder or may occur in patients with poorly compliant bladders. Just as with urinary urgency, urge incontinence may be a sign of occult bladder cancer, and this diagnosis must be considered. Treatment for urge incontinence is distinct from that of stress urinary incontinence in that treatment focuses on measures to relax the bladder (e.g., anticholinergic medical therapy, intravesical Botox, neuromodulation).

Mixed Urinary Incontinence.

Patients often may have urinary urgency with loss of urine and loss of urine with Valsalva maneuvers. These patients should be characterized as having mixed incontinence, and their treatments should reflect both processes; the treatment of one cause of incontinence but not the other may result in exacerbation of symptoms.

Continuous Incontinence.

Patients with continuous urinary incontinence complain of constant wetness in the perineum that is independent of the urge to urinate or maneuvers associated with increased intra-abdominal pressure. Typical of continuous incontinence are processes that bypass the bladder outlet; mainly urinary fistulas. In women, a urinary fistula between the urinary bladder or ureter and the vaginal vault may result in continuous incontinence. Patients complaining of continuous incontinence should be asked about a history of gynecologic surgery, radiation, or traumatic childbirth. Continuous incontinence can be congenital. Such is the case with an ectopic ureter, in which the typically dysplastic upper pole moiety of a duplicated kidney drains into the vaginal or perineum, bypassing the external urinary sphincter. The parents of juvenile patients with ectopic ureters may report unsuccessful toilet training. As adults such patients may complain of urinary incontinence continuously during the day, which may be less severe at night. The absence of urinary incontinence at night may reflect the collection of urine in the saccular upper pole moiety, which is more dependent when the patient is in the recumbent position.

Pseudoincontinence.

Some female patients may experience symptoms similar to continuous urinary incontinence but fail to demonstrate true urinary incontinence. Patients with chronic vaginal discharge may complain of continuous perineal wetness, which may be confused with continuous urinary incontinence. Also, severe labial fusions may result in retention of urine within the vaginal vault and mimic continuous incontinence (Palla et al., 2010). Clearly, a thorough pelvic examination may help identify such causes.

Overflow Incontinence.

Often referred to as paradoxic incontinence, overflow incontinence occurs when the urinary volume within the bladder approaches and exceeds bladder capacity, resulting in an increase in intravesicle pressure greater than urethral outlet resistance. The pressure is released by the decrease in urinary bladder volume associated with incontinence. This is likely to occur at night when the patient is less likely to guard against this incontinence. Guarding is voluntary contraction of the pelvic floor muscles in an attempt to prevent urinary incontinence and can occur with any cause of urinary incontinence. Overflow incontinence can be resolved by treating the outflow obstruction, hence the paradoxic nature of this incontinence. Overflow incontinence is usually present in male patients with prolonged history of bladder outlet obstruction. Because of the gradual progression of symptoms, such patients may not be aware of their obstructive symptoms (as noted earlier).

Functional Incontinence.

Patients with limited mobility or limited access to a toilet or urinal may experience urinary incontinence. Such patients may have intact bladder-outlet anatomy and physiology but may simply be unable to move in time to void in a urinal or toilet. Therefore the urologist must assess mobility in the elderly patient with urinary incontinence.

Elderly patients also may have diminishment of their cognitive abilities and awareness and may lose the social inhibition to soil oneself. Therefore an assessment of cognitive ability should be considered in elderly patients with what ultimately may be volitional urination.

Enuresis.

Urinary incontinence during sleep, known as enuresis, is normal in children up to 3 years of age. It persists in about 15% of children up to 5 years of age and in up to 1% of adolescents up to 15 years of age (Forsythe and Redmond, 1974). Primary enuresis (enuresis that has always been present) persistent beyond 6 years of age should be evaluated by a urologist as ectopic ureter in the female patient. Secondary enuresis (enuresis with onset after child has ceased bedwetting) may be associated with child abuse and bullying (Zhao et al., 2015).

Sexual Dysfunction

Patients with sexual dysfunction often are referred to the urologist. Although sexual dysfunction often is encountered in women with LUTS (Elsamra et al., 2010), the urologist also must be familiar with the different components of sexual dysfunction in men. Men may complain of erectile dysfunction or impotence, when this is merely a symptom of another problem.

Erectile Dysfunction.

The AUA and National Institutes of Health (NIH) Consensus Conference on Impotence in 1993 have defined erectile dysfunction (ED) as the inability to attain and/or maintain penile erection sufficient for satisfactory intercourse. Incidence of ED is significant and can affect more than 50% of men over the age of 40 years. The basic causes of ED (vasculogenic, neurogenic, psychogenic, endocrinologic, and medication side effect) help direct the medical interview. For instance, poorly controlled diabetes mellitus (DM) may result in peripheral neuropathy or vasculopathy, which can affect erectile quality. Antihypertensives, antidepressants, antipsychotic medications, and medications that directly or indirectly affect testosterone levels may all potentially contribute to ED. Therefore a thorough history should explore whether the patient is taking such medications or is afflicted with such ailments that are known to cause ED. Understanding the timing and situational nature of erections in the patient complaining of ED may help identify the cause. For instance, patients who experience situational ED (can have erections with one partner but not another or can attain sufficient erection with visual or manual stimulation) or those who have adequate nocturnal tumescence may have a psychogenic cause. Further, ED can be a harbinger of occult coronary artery disease and should merit consultation to a cardiologist (Nehra, 2012).

Because much of the assessment of ED is subjective, a questionnaire may be a useful tool to quantify and monitor the level of ED. The International Index of Erectile Function (IIEF) and the abbreviated IIEF-6 (also known as the Sexual Health Index for Men [SHIM]) are validated questionnaires often used to quantify and monitor erectile function, orgasmic function, sexual desire, intercourse, and overall satisfaction (Kriston et al., 2008).

Loss of Libido.

ED can be the result of hypogonadism. Hypogonadism can be primary or secondary, and if a low serum testosterone is identified, evaluation of serum prolactin and gonadotropins should be performed. Symptoms of hypogonadism include change in sleep patterns, emotional changes, decreased strength, weight gain, infertility, and ED. The amount of testosterone necessary to maintain libido is usually less than that required for full stimulation of the prostate and seminal vesicles. Therefore patients with adequate ejaculatory volume are unlikely to have hypogonadism severe enough to cause loss of libido. Depression, several medications, or severe medical illnesses (e.g., cancer) can result in loss of libido.

Because libido is a subjective measure, clinical questionnaires may be the best tool to quantify and monitor a patient's sexual desire. Several validated questionnaires have been produced to aid in the evaluation for hypogonadism: the Androgen Deficiency in Aging Questionnaire (ADAM), the Aging Male Survey, and the Massachusetts Male Aging Study Questionnaire (Wiltink, 2009). Although these surveys may not correlate with serologic hypogonadism, the Hypogonadism Related Symptom Scale may offer greater sensitivity and specificity based on serum testosterone levels (Wiltink, 2009).

Premature Ejaculation.

According to the International Society of Sexual Medicine Guidelines, premature ejaculation is either less than 1 minute (if lifelong) or 3 minutes (if acquired) and must be associated with inability to delay ejaculation and with negative personal consequence (Althof et al., 2014). Unfortunately, many patients presenting with the complaint of premature ejaculation often have unrealistic expectations for intravaginal ejaculatory latency time. Intravaginal ejaculatory latency time (IELT) was evaluated in five countries, and median time to ejaculation was 5.4 minutes in one study published in 2005. Further, a survey of sexual therapists supported IEJT of 1 to 2 minutes as too short but 3 to 7 minutes as adequate and 7 to 12 minutes as desirable (Corty and Guardiani, 2008). In patients with true premature ejaculation, vaginal quieting or sexual counseling should be offered. Although possibly helpful, treatment with a serotonin reuptake inhibitor should be offered infrequently (Montague et al., 2010). Because of latency to erectile function postejaculation, some patients with erectile dysfunction actually may have normal latency in attaining erections postejaculation.

Failure to Ejaculate.

Several causes exist for anejaculation. Androgen deficiency, sympathetic denervation, use of pharmacologic agents, and a history of bladder neck/prostate surgery can result in decreased volume of ejaculation or anejaculation. Therefore the patient should be assessed for hypogonadism. Systemic hypogonadism (see earlier) or local decreased stimulation of prostate and seminal vesicles as seen with 5-alpha-reductase inhibitor administration often used for alopecia or enlarged prostate can result in lower volume ejaculate. A history of retroperitoneal surgery, especially retroperitoneal lymphadenectomy, as is done for testicular cancer, should be established because transection of the sympathetic nerve fibers results in anejaculation. Alpha-adrenergic antagonists (e.g., tamsulosin) and surgeries that affect the bladder neck (e.g., TURP) may result in retrograde ejaculation. Patients with advanced diabetes also may experience anejaculation.

Anorgasmia.

Orgasm is the euphoria associated with a series of muscular contractions in the genital region and the release of endorphins. It usually is associated with ejaculation in men. Orgasm can occur without erection or ejaculation in men (e.g., postprostatectomy). Absence of orgasm can be due to psychogenic causes and several medications used to treat psychiatric ailments. In cases of impaired pudendal nerve function (e.g., diabetic peripheral neuropathy) anorgasmia can occur as well. Such patients may benefit from neurologic evaluation (e.g., vibratory testing to assess penile sensation) or referral to a sexual counselor.

Hematospermia

Hematospermia is the presence of blood in the ejaculate. With rare exception it is due to nonspecific inflammation of the prostate or seminal vesicles and usually resolves spontaneously. This can be associated with ejaculation after a long duration of sexual abstinence. If blood is persistent beyond several weeks, the urologist should consider an evaluation including a genital examination, digital rectal examination, prostate specific antigen, cystoscopy, and urine cytology to exclude GU tuberculosis or cancer.

Pneumaturia

Pneumaturia is the passage of gas within the urine. This can sometimes be an alarming finding for the patient because this may interrupt the urinary flow and sound like flatus from the urethra. Pneumaturia is most commonly due to a fistula between the gastrointestinal system and the bladder. Therefore such patients should be screened for Crohn disease, enteritis, or history of recent intra-abdominal surgery or radiation. Rarely, pneumaturia may be due to gas-forming bacteria within the urinary tract. Therefore patients also should be screened for history of severe urinary tract infections or immunocompromised states.

Urethral Discharge

This is the most common symptom of sexually transmitted infection (STI). Patients should be screened for high-risk sexual behavior. Bloody discharge may be concerning for urethral carcinoma.

Fevers and Chills

It should be determined, in a patient who reports fevers, if the fevers are subjective or if they were measured objectively with a thermometer. The method by which the temperature was obtained (thermometer used orally vs. rectally vs. auricular or temporal scanner) can affect the accuracy of the measured temperature compared with the core temperature and may be important to note in pediatric patients. Rigors (or chills) may or may not be associated with fevers but can be independently concerning for bacteremia or other severe infection. The severity and site of infection may affect whether a patient will have fevers or chills. For example, cystitis rarely causes fever, but the diagnosis of pyelonephritis often requires presence of a fever. A patient with fevers and chills may signal a systemic response to an infectious process or sepsis and merit further evaluation or even possibly hospitalization. Fevers and chills in the elderly or immunocompromised should be especially concerning.

Constitutional Symptoms

Constitutional symptoms are fevers, chills, night sweats, anorexia, weight loss, fatigue, or lethargy. Sometimes these are referred to as B symptoms, borrowed from non-Hodgkin lymphoma staging. Such symptoms can signal the presence of advanced inflammatory, infectious, or malignant processes such as GU tuberculosis or advanced bladder cancer.

Medical History

It is incumbent upon the urologist to obtain an accurate medical history because many of the patients’ medical problems may have urologic implications. Moreover, it is important to understand the severity of the medical illness and the compliance with treatment. For instance, knowing that patients are afflicted with

DM is important, but so is knowing if their glucose is well controlled with or without insulin and if they have peripheral neuropathy associated with their diabetes. (A good question to ask is, “Is a recent HgbA1C available?”)

Patients often may not be aware of all their medical conditions. Soliciting input from a family member or reviewing a recent note from the primary care provider also may help. A good place to start is to assess the patient's medication list and determine medical illnesses based on that. However, this can be misleading because several medications may be administered for different reasons (e.g., hydrochlorothiazide for hypercalciuria vs. hypertension) and patients may not be compliant with all their medications.

Even though the patient, family member, or recent medical documentation may not mention a medical illness, the urologist must remain vigilant to ensure there are no undiagnosed medical conditions that can adversely affect the patient or any subsequent urologic treatment. The classic example of this is occult coronary artery disease in the urologic patient who may require surgery soon. Although patients may have never had a “heart attack,” they may, if prompted, report shortness of breath or chest pain with activity, and this may be a signal of undiagnosed coronary artery disease. Another example is a large patient with a large collar size who does not provide a medical history of obstructive sleep apnea, but, if prompted, his spouse may report nighttime snoring and irregular breathing or daytime fatigue in the patient. Clearly, the diagnosis of coronary artery disease and obstructive sleep apnea, among others, can have implications for treatment.

Performance Status

The functional ability of patients is a testament to their overall health and their ability to withstand challenging treatments such as invasive surgery or chemotherapy. At the most basic level, the activities of daily living (ADLs), which include dressing, eating, ambulating, toileting, and hygiene, and the instrumental ADLs, which include cleaning and maintaining a house, managing money, preparing meals, shopping, and community participation, can be easily assessed during the perioperative setting to help determine risk for surgery. Levitt et al. evaluated nearly 200 patients who underwent percutaneous nephrolithotomy, identified deficiency in ADLs in 16% of patients, and identified deficit in ADLs as an independent predictor of complications better than Charlson Comorbidity Index or the American Society of Anesthesiology Score (Leavitt et al., 2014).

Several performance status scales have been developed and are used mostly for oncologic purposes. These scales include the Eastern Cooperative Oncology Group score and Karnofsky performance status grade, which classify patients according to their ability to perform physical activity of a strenuous or nonstrenuous nature, ability to self-care, ability to stay out of bed, or moribund status. Using such scales may be beneficial particularly in transmitting an impression of overall health to another provider; they are a clear factor in health assessment.

Past Surgical History

Prior surgery in a patient may have clear impact on the patient's assessment and subsequent treatment options. Prior surgeries, related to GU anatomy of interest or not, may indicate additional adhesions or obliteration of surgical planes, which can render subsequent surgery difficult. For example, a patient with extensive intra-abdominal surgery undergoing subsequent laparoscopic surgery may benefit from Hasson technique or visual port access as opposed to Veress needle access (Gaunay, 2016). Further, abstracting surgical anatomic details in a prior operative report may help the surgeon ascertain the utility of a subsequent procedure. For instance, a patient who underwent a prior TURP may have an operative report that includes TURP, but the operative details may reveal that only a channel TURP was performed, therefore opening the possibility that a subsequent TURP may be beneficial. Further, a prior operative report may provide vital information regarding anatomy or other difficulties encountered.

Medications

A thorough knowledge of medications can provide information regarding the presence and severity of a medical illness, possible cause for urologic complaints from medication side effects, and a target for cessation or adjustment in the perioperative period. Several examples to highlight these principles are as follows:

1. A patient with diabetes on several medications and large doses of insulin may have severe diabetes and be more likely to have peripheral neuropathy, even if he or she is not on a medication for peripheral neuropathy.
2. A patient on tamsulosin may complain of anejaculation or

lightheadedness, not knowing the side effect profile of this medication.

3. A patient with hematuria on anticoagulation or antiplatelet therapy may benefit from temporary cessation (in addition to a full evaluation).

This last example can be used to highlight several pitfalls with poor medical history taking and its impact. For example, a patient on baby aspirin may be taking this for primary coonary artery disease prophylaxis or for prevention of coronary artery stent thrombosis. Clearly this would have consequence regarding when and if such medications should be ceased. See Table 1.2 for a list of drugs associated with urologic side effects.

TABLE 1.2

Drugs Associated With Urologic Side Effects

UROLOGIC SIDE EFFECTS	CLASS OF DRUGS	SPECIFIC EXAMPLES
Decreased libido	Antihypertensives	Hydrochlorothiazide
Erectile dysfunction	Psychotropic drugs	Propranolol
		Benzodiazepines
Ejaculatory dysfunction	α-Adrenergic antagonists	Prazosin
		Tamsulosin
		α-Methyldopa
	Psychotropic drugs	Phenothiazines
		Antidepressants
Priapism	Antipsychotics	Phenothiazines
	Antidepressants	Trazodone
	Antihypertensives	Hydralazine
		Prazosin
Decreased spermatogenesis	Chemotherapeutic agents	Alkylating agents
	Drugs with abuse potential	Marijuana
		Alcohol
		Nicotine
	Drugs affecting endocrine function	Antiandrogens
		Prostaglandins
Incontinence or impaired voiding	Direct smooth muscle stimulants	Histamine
		Vasopressin
	Others	Furosemide
		Valproic acid
	Smooth muscle relaxants	Diazepam

	Striated muscle relaxants	Baclofen
Urinary retention or obstructive voiding symptoms	Anticholinergic agents or musculotropic relaxants	Oxybutynin
		Diazepam
		Flavoxate
	Calcium channel blockers	Nifedipine
	Antiparkinsonian drugs	Carbidopa
		Levodopa
	α-Adrenergic agonists	Pseudoephedrine
		Phenylephrine
	Antihistamines	Loratadine
		Diphenhydramine
Acute renal failure	Antimicrobials	Aminoglycosides
		Penicillins
		Cephalosporins
		Amphotericin
	Chemotherapeutic drugs	Cisplatin
	Others	Nonsteroidal anti-inflammatory drugs
		Phenytoin
Gynecomastia	Antihypertensives	Verapamil
	Cardiac drugs	Digoxin
	Gastrointestinal drugs	Cimetidine
		Metoclopramide
	Psychotropic drugs	Phenothiazines
	Tricyclic antidepressants	Amitriptyline
		Imipramine

Allergies

Patients must be asked about allergies during the initial encounter, and allergy lists should be verified for accuracy on subsequent encounters. The inciting medication and the reaction should be written because many patients confuse allergy with side effect (e.g., red-man syndrome for vancomycin or upset stomach with antibiotics). Such medical allergies should be highlighted in the electronic medical record (EMR) to prevent inadvertent prescription or administration of such medication.

Social History

The social history includes an evaluation of tobacco, alcohol, and illicit drug consumption. The agent and the method of use have medical implications. Tobacco can be chewed, smoked, or vaped. A patient who chews tobacco may still benefit from a nicotine patch during a hospitalization but may not necessarily have the urothelial cancer risk associated with smoking. Vaping, which may not have many of the carcinogens associated with combustion, may still provide derivatives of nicotine that promote malignant changes in urothelial and lung cell lines (Lee et al., 2018), although the long-term effect is still unknown.

Alcohol use should be evaluated because it may increase oncologic risk and risk for liver disease, which have clear implications for patient care. Alcohol use also can affect LUTS and sexual function. More acutely, a patient who ingests significant amounts of alcohol and is hospitalized may suffer from life-threatening withdrawal if a prophylactic measure such as Clinical Institute Withdrawal Assessment for Alcohol (CIWA) or alcohol replacement is not ordered. Patients with heavy alcohol ingestion often understate the amount of alcohol consumed. Anticipating this can allow for the provider to better order prophylactic measures.

Illicit Drug Use

There are many classes of illicit drugs (e.g., cocaine, narcotics, methamphetamines), all of which can be consumed via a myriad of modes. Knowing the agent used and the mode can prepare the provider for anticipating challenges in subsequent care in addition to the risk for communicable diseases if the intravenous mode is used. Because of the illicit nature and social stigma of such drugs, many patients may not be forthright about use; therefore the provider may need to establish high levels of trust to encourage the patient to divulge such information. Alternatively, review of prior medical records can help ascertain these risky habits.

Sexual Relations

Patients may engage in sexual behavior with a single person or multiple people of the same or different gender. The physician should not presume a monogamous, heterosexual relationship. Nonaccusatory questions such as, “Do you partake in sexual relations with men, women, or both? A single partner or many?” may allow the patient to provide an accurate answer without being defensive regarding alternative lifestyle. Clearly such information is important to assess for risk for STI and to assess social support structure.

Domestic Station

Typically patients are asked if they are married or single and who lives in the home with them. It is also beneficial to understand if the patient has family or friends who live nearby. Assessing where the patient lives and with whom is important for planning subsequent care. A patient with little or no social support may not fare well after a complex, life-altering surgery. Further, this information may provide insight regarding what treatment options a patient may find unacceptable (e.g., an elderly man who is the sole caretaker of an elderly handicapped woman may not be willing to undergo major surgery with long convalescence). Screening for domestic violence or other unsafe domestic situation should be completed at this time as well.

Occupation

Understanding the patient's current or prior occupations provides the urologist with greater insight into the patient's world-view and socioeconomic status as well as possible industrial exposure to possible carcinogenic agents.

Family History

Many diseases with urologic manifestations have a clear genetic component, and their mode of transmission (e.g., autosomal dominant) is well defined. Examples include adult polycystic kidney disease, tuberous sclerosis, von Hippel-Lindau disease, renal tubular acidosis, and cystinuria. Other diseases, such as prostate cancer or urolithiasis, have a well appreciated familial component, although the precise pattern of inheritance is not understood. Often the age at diagnosis of the family member can direct screening age. A recent study by Bratt et al. evaluated nearly 52,000 Swedish men with fathers or brothers with prostate cancer and identified an increased risk of prostate cancer incidence with a brother diagnosed (30% vs. 13% in the general population) and a father and a brother diagnosed (48% vs. 13% in the general population) (Bratt et al., 2016; Nordström, 2016). Therefore identifying not only the presence of disease in the family but also the frequency within the family may be important in screening such patients for disease.

Review of Systems

A review of systems is a comprehensive system-based checklist to determine if there are any other complaints or ailments that the patient may have. This may be a valuable opportunity to identify important issues that may not be related to the chief complaint.

Physical Examination

A complete and thorough physical examination is essential for any patient encounter. It often allows the urologist to select the most appropriate next step.

Vital Signs

Physical examination should start with a general set of vital signs. The objectively measured temperature, heart rate, blood pressure, respiratory rate, and pain rating can identify immediately the critically ill patient who may not necessarily be best served by waiting for an appointment. In the office setting, a defined normal range should be established, with patients beyond this acceptable range referred to the physician immediately to triage. All office staff should be assigned a role in assessing patients for critical illness or severe distress. In my clinical practice, we have encountered such patients who are profoundly hypotensive or tachycardic who benefited from rapid transportation to the emergency room.

Some have advocated for a rapid screening tool used to assess distress and measures set in place to provide such patients with prompt attention from social worker, mental health professional, or pastoral care (JNCCN, 2003). Such a tool can be considered a sixth vital sign and can help decrease the anxiety and distress within an already stressful waiting room.

General Appearance

Every medical student is instructed regarding the four modes of physical examination: inspection, auscultation, percussion, and palpation. Inspection is the first mode and can be applied to the entire patient at the onset of the encounter. Several general observations should be made, including level of pain or emotional distress, nutritional status, socioeconomic status and appropriateness in dress, overall strength or mobility of patient, appearance of skin quality, and quality of dentition. Often patients' appearance is compared with the stated age and noted accordingly (e.g., an ill patient or one with poor self-care may appear much older than stated age). Several diseases may have stigmata, such as jaundice with advanced liver disease, buffalo hump or skin striae with Cushing disease, exophthalmos with Graves disease, fibrofolliculomas in patients with Birt-Hogg-Dube syndrome, cogwheel rigidity in Parkinson disease, and apparent erection with priapism.

A preliminary assessment of frailty and nutritional status can be made upon general inspection. Frailty has been defined as the “excess vulnerability to stressors, with a reduced ability to maintain or regain homeostasis after a destabilizing event” by the American Geriatric Society (Xue, 2011). Several simple tools have been established and validated as markers for frailty. The gait speed (Dudzińska-Griszek et al., 2017) and get-up-and-go test (Pamoukdjian et al., 2015) as well as grip strength can be obtained easily as part of the standard encounter. Calf circumference (Landi et al., 2014) also has been assessed with an inverse relationship with frailty.

Many other clues can be obtained from the general physical examination. The quality of the dentition or moist mucous membranes can be a sign of health and hydration, respectively. For morbidly obese patients or patients with skeletal deformities, I have found that positioning the patient in the anticipated operative position while in the office prevents any surprises in the operating room.

Kidneys

The kidneys are located in the retroperitoneum and surrounded by the psoas muscle, diaphragm, oblique muscles, and the peritoneum with its contents. Aside from very large renal masses in small children or very thin adults, the kidneys should not be visible. In fact, the kidneys may be difficult to palpate under normal conditions. Because of the location of the liver, the right kidney may be inferior to the level of the left kidney, and palpation of the lower pole can be appreciated on deep inspiration.

The overlying skin in the upper quadrant and the costovertebral angle should be inspected, however, for any superficial lesions that may be causing “flank pain.” Assessment of the skin sensation for pain, temperature, and light touch can be performed with a spoke-wheel or pin, cool object, and fine brush, respectively. Patients with herpes zoster may experience prodromal hyperesthesia before eruption of vesicles.

Bimanual examination, or renal ballottement, can be performed by placing the nonexamining hand posteriorly at the costophrenic angle and palpating for the kidney with the examining hand through the anterior abdominal wall (Fig. 1.1). Deep inspiration can help inferiorly displace the kidney to aid in exposure. In neonates and infants, ballottement can be performed between the thumb, placed anteriorly on the abdomen, and remaining four fingers, placed posteriorly at the costovertebral angle. Often large flank masses originate from the kidney in neonates, and transillumination may be feasible. If such a mass is fluid filled (cyst or hydronephrosis), then a dull reddish glow can be appreciated. However, if the flank mass is from a solid process (tumor or polycystic kidney), then no glow will be appreciated.

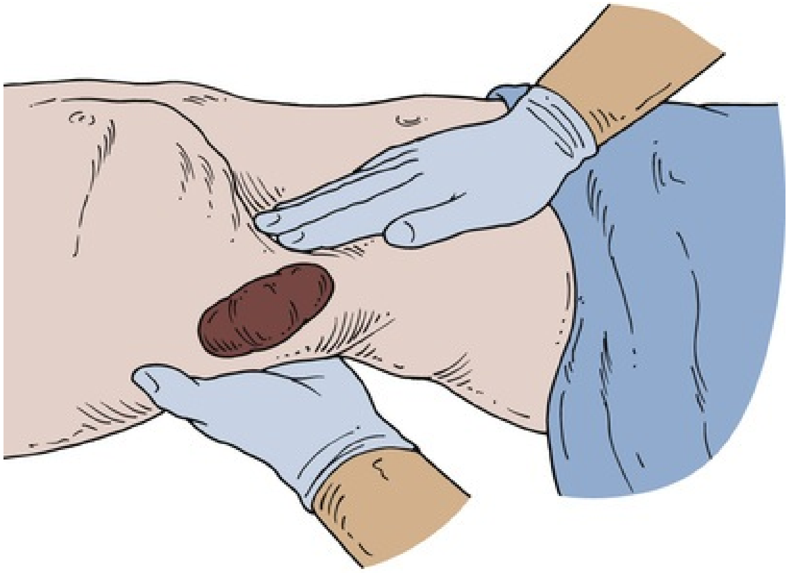

FIG. 1.1 Bimanual examination of the kidney.

Turbulent vascular flow within the renal artery, suggestive of renal artery stenosis or large renal arteriovenous fistula, theoretically can be observed with auscultation. However, if such a bruit is appreciated, it is nonspecific for renal artery source and should be evaluated further with appropriate imaging (ultrasound with Doppler or angiography). Percussion of the kidneys often refers to the assessment of pain when the base of a closed hand of the examiner contacts the costovertebral angle. The examiner should approach this examination technique gently and avoid using excessive force because a simple tap may elicit the positive sign.

Bladder

The bladder is located within the pelvis and can be palpable only as the bladder distends to a level above the pubis, typically greater than 150 mL. At a volume of approximately 500 mL, the bladder may be visible as a lower midline abdominal mass in thin patients. Percussion starting at the level of the pubic symphysis and ascending toward the umbilicus can help determine the level of distention because the pitch may change from dull to resonant beyond the bladder. Ballottement also can aid in palpation of the bladder.

A bimanual examination (Figs. 1.2 and 1.3) is performed to assess the mobility of the bladder and is the standard of care for examination of patients with large bladder tumors postresection (Chang et al., 2016). Even in the era of CT and MRI, a bimanual examination can improve upon the performance of these images for the prediction of pT3 disease (Rozanski et al., 2015) and was found to be an independent predictor of pT3 disease on multivariate analysis.

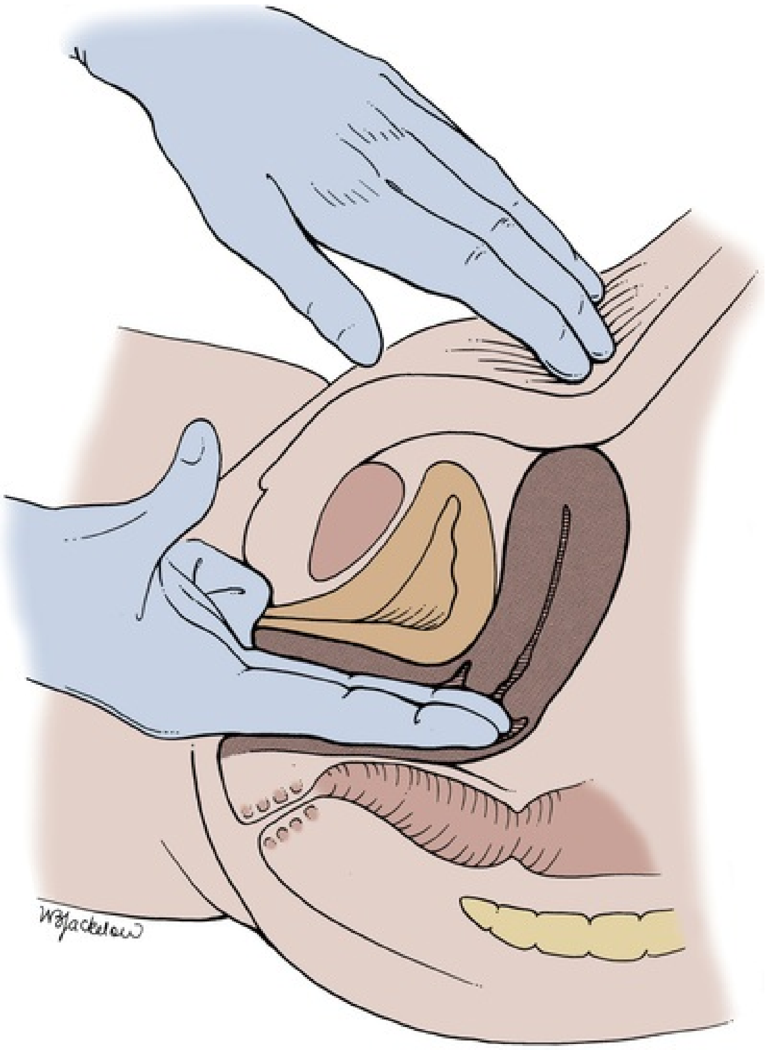

FIG. 1.2 Bimanual examination of the bladder in the female. (From Swartz MH: *Textbook of physical diagnosis*, Philadelphia, 1989, Saunders, p 405.)

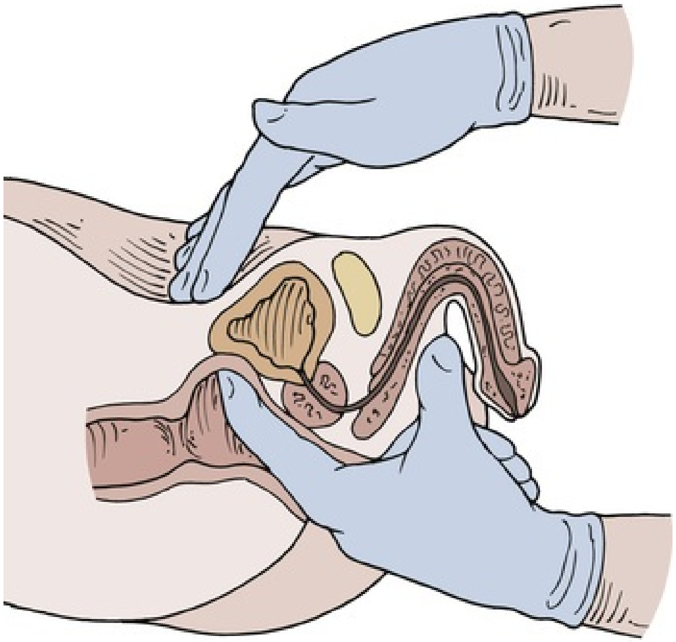

FIG. 1.3 Bimanual examination of the bladder in the male.

Penis

The phallus should be inspected for hair distribution, lesions on the skin, and the presence or absence of a foreskin. In the pediatric population, Tanner stage should be noted. Lesions on the penile skin can include superficial vesicles suggestive of herpes simplex or ulcerative lesions concerning for other sexually transmitted diseases or squamous cell carcinoma of the penis or venereal warts (condyloma acuminata) concerning for human papillomavirus (HPV) infection. Often patients may inquire about prominent vasculature on the phallus, particularly in children, and this is often normal.

The foreskin, if present, should be retracted to ensure that there are no penile tumors; most penile tumors involve the prepuce or the glans penis. The urethra should be inspected for location and absence of stenosis and presence of urethral discharge. Discharge, if present, should be characterized, and ideally a sample should be obtained if there is concern for STI. If hypospadias (ectopic location of urethral meatus on ventral aspect of penis) is identified, location and caliber of urethral meatus are noted (e.g., mega-meatus). A rare finding would be epispadias, in which the meatus is located on the dorsal aspect of the penis, although this is often seen with other profound GU anomalies such as bladder exstrophy. Palpation of the phallus can reveal dense subcutaneous plaques on the underlying fascia, which is concerning for Peyronie disease, which may also be demonstrated as curvature in the erect penis. Palpation of the urethra, if tender, is suggestive of periurethritis. Spongiofibrosis, which has implications for urethral reconstruction, can be palpated along the corpora spongiosum only if it is severe.

Scrotum and Contents

The scrotum contains the testicles and spermatic cord structures. The scrotal skin, which has hair and sebaceous glands, should be assessed for infectious processes (e.g., tinea cruris, cellulitis, pustules), which are more common, and malignant processes (squamous cell carcinoma typical of chimney sweeps), which are rare. Often such infectious processes are of minimal clinical consequence. Tinea cruris and cellulitis may be manifested by erythema and tenderness, whereas an abscess may demonstrate an area of fluctuance or purulent drainage. In the immunocompromised patient or in patients with limited capacity for self care, such infections can progress to Fournier gangrene, which is typified by necrotic “black” skin, foul odor, dishwater discharge, and crepitus.

The impression of the testicles should be assessed for their size and orientation. Although one testicle may be slightly inferior to the other, they should be of similar size and in the vertical orientation. However, in a patient with unilateral testicular pain, the testicle with a foreshortened cord and a horizontal lie can be concerning for testicular torsion. The absence of a cremasteric reflex (light touch to inner thigh resulting in cremasteric muscle contraction and ascension of the ipsilateral testicle) is a very specific sign for testicular torsion in pediatric patients.

Palpation of the testicles, epididymi, and spermatic cords should begin with the normal testicle. The testicles have a firm, rubbery consistency with a smooth ovoid surface. Typical size is 6 cm in length and 4 cm in width with variation seen among different races. Testicular size can be better assessed with an orchiometer (goniometer). Gliding the testicles between the examiner's fingers of both hands allows for palpation of the contour of the surface. A testicle that is small can be suggestive of prior infarct, surgery, hypogonadism, or endocrinopathy such as Klinefelter disease. Tenderness of the testis or the epididymis may indicate orchitis or epididymitis, respectively. Masses in the testes are hard and obliterate the smooth contour of the testis and should be considered testicular cancer till proven otherwise. Epididymal masses, on the other hand, which obliterate the distinct ridge of tissue posterior to the testis, are almost always benign. The vas deferens should be palpable bilaterally on each cord, high in the scrotum, and feel like a thick al dente linguini. Transillumination can be performed in the scrotal mass to assess for fluid content (e.g., hydrocele). To accentuate a varicocele, typically described as a "bag of worms," inspection and palpation of the scrotum should be performed with the patient supine, standing, and standing with Valsalva.

Examination for hernia can be performed by placing the examiner's index finger over the testis and invaginating the scrotum up toward the external ring (Fig. 1.4). The other hand is used to palpate over the internal ring and Hesselbach triangle (bordered by the inferior epigastric artery, the inguinal ligament, and the midline). The patient is instructed to perform Valsalva maneuver at that point, and the examiner assesses for a hernia as a distinct bulge that descends against the tip of the index finger. In children, the presence of a hernia can be appreciated by assessing for the "silk glove" sign. The potential space within the hernia sac allows for the hernia sac to roll over itself, resembling the sensation of rolling over the finger of a silk glove.

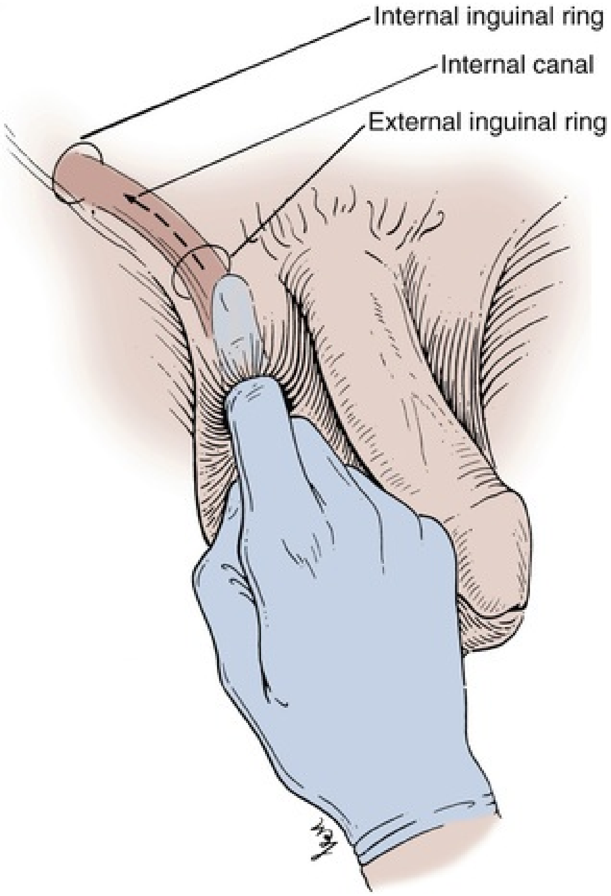

FIG. 1.4 Examination of the inguinal canal. (From Swartz MH: *Textbook of*

physical diagnosis, Philadelphia, 1989, Saunders, p 376.)

Digital Rectal Examination

The digital rectal examination (DRE) can be performed for assessment of prostate size, detection or provocation of prostatitis, and screening for prostate cancer. A DRE with a concurrent lower abdominal exam (bimanual examination) typically is performed in a patient who has undergone a transurethral resection of bladder tumor while still anesthetized. A gentle DRE also can be performed in neonates with disorders of sexual differentiation to evaluate for internal müllerian structures (e.g., uterus). Although prior recommendations included DRE for men ages 40 and older, current AUA guidelines state that prostate cancer screening should be offered in men of average risk from the age of 55 to 69 at an interval of every 2 years.

To have a DRE, the patient should be standing with feet shoulder width apart and bent nearly 90 degrees at the waist. The patient can benefit from using the table to support this position by placing his hand or elbows on the table. Alternatively, the patient may be in a lateral decubitus position, flexed at the hips and knees, on the examining table. The patient is to be reassured throughout this part of the examination. The examiner's nondominant hand is used to spread the gluteal folds and expose the anus, which should be inspected for hemorrhoids or other lesions. The examiner's gloved finger with adequate lubrication then is advanced gently through the anus with the nondominant hand placed on the patient's anterior thigh or lower abdomen to provide gentle counter-traction. The finger is advanced until the prostate is palpable. The normal prostate is the size of a chestnut and should feel soft, similar to that of the contracted thenar eminence. Nodular firmness (which feels like a flexed knuckle) is concerning for prostate cancer and should merit biopsy. Adequate supplies to allow for the patient to cleanse himself and privacy should be provided before concluding the encounter.

Pelvic Examination in the Female

The female pelvic exam is performed by the urologist to evaluate for pelvic organ prolapse, urinary incontinence, dyspareunia, blood per urethra or vagina, and anterior vaginal masses. The patient should be instructed to disrobe from the waist down and wear an examining gown and then is placed on the examining table. Footrests (stirrups) are used to flex and abduct the thighs and flex the knees. If a male urologist is to perform a pelvic examination, this must be done with the presence of a female chaperone (nurse or medical assistant).

Visual inspection of the external genitalia and introitus should evaluate for atrophic changes, erosions, ulcers, discharge, or genital warts. The labia should be separated, and the urethra inspected for prolapse, caruncle, hyperplasia, or cysts. Ideally with a full bladder, the patients should be instructed to perform Valsalva maneuver to elicit stress urinary incontinence. The insertion of a half of a speculum may allow for appropriate visualization of one wall of the vagina. With Valsalva, the examiner can evaluate for prolapse from the bladder, apex, or rectum. Palpation of the urethra can reveal a mass or promote a discharge, which may raise suspicion for urethral diverticulum. Bimanual examination should be performed by placing two of the examiner's fingers of the dominant hand into the vaginal vault (one finger if the introitus is small) and placing the nondominant hand over the lower abdomen and palpating for pelvic mass or tenderness. The female pelvic exam is intrusive and should be performed based on clinical suspicion and not for screening. For screening examinations the patient should be referred to the gynecologist. Children, adolescents, and young women should rarely need a pelvic examination from the urologist.

Neurologic Examination

A sensory dermatome map can help localize the location of a neurologic deficit (Fig. 1.5). Most sensory deficits of the genitalia and perianal area indicate a lesion in the sacral nerves or their root. Evaluation of bulbocavernosal reflex can indicate whether this reflex arc is intact. This reflex tests the integrity of the spinal cord–mediated reflex arc involving S2-S4. Squeezing the glans penis or clitoris should result in immediate contraction of the anal sphincter muscles, which can be appreciated during a DRE. Alternatively, in patients with a Foley catheter indwelling, tugging on the Foley catheter can elicit this response.

Special Populations

Children

Although pediatric urology practice includes the care of infants, toddlers, children, adolescents, and young adults (sometimes up to age 26 years), the needs of each of these subgroups of pediatrics may be very different. Infants and toddlers may not be able to provide an HPI; therefore any clinical questions are directed toward the parents or guardians. Adolescents and young adults likely require some input from the parent or guardian but will also require some privacy. Questions pertinent to social history (alcohol, smoking, drugs, sexual activity) should be directed to the patient in private. The examination of infants, toddlers, and children should include a comfortable, nonthreatening environment. Often pediatric urologists do not wear a white coat because of the association of white coats with painful doctor's visits and immunizations. The examination ideally should be performed with the help of the family member to decrease the child's distress with the exam. Children are particularly sensitive to the cold and pain, and maneuvers resulting in this should be reserved for the end of the visit.

Elderly

Geriatric patients require much care and attention because they may not have the same physical and cognitive ability as younger patients. Again, a comfortable, nonthreatening environment should be provided. As with pediatric patients, input from the family member or caretaker may be invaluable; however, privacy should not be compromised. Elderly patients may have decreased mobility, and the examination room should be set up for this: lower examination tables, possibly Hoyer lifts for those who are wheelchair bound, blankets and pillows to facilitate comfortable position. Elderly patients can have pseudodementia, which is depression of cognitive affect and ability related to an illness. Therefore it is very important that baseline physical and cognitive abilities be assessed and occult illness be considered.

Transgender and Gender Nonbinary People

It is estimated that 5 in 1000 persons in the United States are transgender or gender nonbinary. These people may have reluctance to seek medical care because of the social stigma associated with their lifestyle. Regardless of the caretaker's belief system, such people should still be offered compassionate medical care as would be afforded to any other person. Caretakers should demonstrate cultural humility and meet their patients without preconceptions.

A few definitions are beneficial to help standardize documentation and communication. Sex often refers to chromosomal or gonadal sex, which is assigned from birth, whereas gender (or gender identity) is a person's perceived internal self. A transgender person's gender is different from the sex attributed at birth. A transgender woman is a male at birth but has a female gender identity. A transgender man is a female at birth but has a male gender identity. Transgender masculine or feminine connotates a directionality and not a full conversion, towards the gender identity. Patients who do not identify with a single gender are referred to as nonbinary. The patient's name, the term “the patient,” or neutral pronouns (*they, them,* or *their* instead of *he/she* or *his/hers*) are used in such patients. Cross-dressing refers to patients who wear clothing of the opposite sex assigned to them at birth for entertainment, self-expression, or sexual pleasure. Sexual orientation is independent of all these prior definitions and is not related to gender identity.

Currently many offices may not be set up ideally to treat transgender patients in a culturally neutral way. Office staff should be educated regarding proper terminology and refrain from expressing judgment. The electronic medical record ideally should have gender identity as a two-step question: gender identity and assigned sex at birth. Further, the presence of gender-neutral bathrooms can decrease some of the tensions associated with caring for transgender and non-transgender patients.

Secondary sexual characteristics should be identified and noted. Patients should be asked what steps they have taken toward their gender, restricted to cross-dressing, hormonal therapy, or gender-affirming surgery (and its extent). Examination of gender-sensitive areas (breasts and genitalia) should be reserved for purpose, as they should in non-transgender patients. Explaining the anatomy and the steps for each exam may help decrease the anxiety associated with a pelvic exam. Establishing a trusting physician-patient relationship before delving into a pelvic exam also may prove beneficial. Pharmaceutical adjuncts include the administration of a benzodiazepine before exam to help decrease anxiety associated with the exam or administration of topical estrogen creams for 1 to 2 weeks before the exam to help counter the effect of exogenous androgens.

Conclusion

The history and physical examination are the foundation of any urologic encounter. Obtaining a thorough history and performing a proper physical examination can help detect urologic issues that are not detectable by other means (laboratory or radiology). Having a broad differential diagnosis can help direct the HPI. Understanding nuances associated with elderly, pediatric, and transgender patients can help the practitioner offer urologic care to a wider population.

Key Points

- The urologist should perform a history and physical examination in a systematic approach, such that pertinent information can be obtained in a reliable fashion to help ascertain diagnosis or at least direct subsequent laboratory and/or radiographic evaluations.
- A broad differential diagnosis is beneficial and can help direct the history of present illness.
- Several disease states and medications have urologic side effects and can have implications for subsequent urologic surgery.
- Physical examination should be thorough but not unnecessarily invasive.
- Special considerations must be made for children, the elderly, and transgender patients.

Evaluation of the Urologic Patient

Testing and Imaging

Erik P. Castle MD, Christopher E. Wolter MD, Michael E. Woods MD

The urologist has various serum, urinary, and radiologic studies available to complement the physical examination and perform a thorough and comprehensive evaluation of the urologic patient. Knowing when to order these studies based on the history and physical findings is crucial to identifying underlying pathology. Urinalysis is one of the more commonly performed laboratory studies, and in some cases the urologist will perform the urinary dipstick and microscopy analysis in the office during the evaluation. Furthermore, many office procedures such as uroflowmetry and cystourethroscopy may be incorporated into the evaluation. It is these laboratory and office studies that may be combined with radiologic testing during the evaluation of the urologic patient.

Urinalysis

The urinalysis is a fundamental test that should be performed in all urologic patients presenting with urinary symptoms and complaints. **Evaluation of voided urine includes gross examination, dipstick chemical analysis, and microscopic analyses.**

Collection of Urinary Specimens

Males

To avoid contamination in the male patient**, a midstream urine sample is obtained.** Retraction of the foreskin and cleansing of the glans and urethral meatus is performed. The male patient begins urinating into the toilet and then places a wide-mouth sterile container under his penis to collect a midstream sample.

A variety of methods are available to identify a potential source of infection if not clearly from the bladder. One traditional test is the use of four aliquots to differentiate bacteria from the bladder, urethra, and prostate. **These aliquots can be designated Voided Bladder 1, Voided Bladder 2, Expressed Prostatic Secretions, and Voided Bladder 3 (VB1, VB2, EPS, and VB3).** The VB1 specimen is the initial 5 to 10 mL of urine voided, whereas the VB2 specimen is the midstream urine. The EPS is the secretions obtained after gentle prostatic massage, and the VB3 specimen is the initial 2 to 3 mL of urine obtained after prostatic massage. The value of these cultures for localization of urinary tract infections (UTIs) is that the VB1 sample represents urethral flora, the VB2 sample represents bladder flora, and the EPS and VB3 samples represent prostatic flora. The VB3 sample is particularly helpful when little or no prostatic fluid is obtained by massage. The four-part urine sample is particularly useful in evaluating men with suspected bacterial prostatitis (Meares and Stamey, 1968). An alternative is to obtain two aliquots of urine, one before prostatic massage and one following prostatic massage (Nickel et al., 2006). The two-aliquot technique may be easier in some cases and has been demonstrated in one study to show concordance with the four-aliquot test described by Meares and Stamey.

Females

Obtaining a sterile voided urine collection can be a challenge in the female patient. The standard midstream urinalysis in the female patient should be obtained after separating the labia and cleansing the vaginal introitus and external urethral meatus. This is an appropriate method for the routine collection. However, **in the female patient with suspected recurrent UTIs or a history of antibiotic-resistant infections, a catheterized urine sample should always be obtained.**

Neonates and Infants

The usual way to obtain a urine sample in a neonate or infant is to place a sterile plastic bag with an adhesive collar over the infant's genitalia. However, these devices may not be able to distinguish contamination from true UTI. Whenever possible, **all urine samples should be examined within 1 hour of collection and plated for culture and sensitivity if indicated.** If urine is allowed to stand at room temperature for longer periods, bacterial overgrowth may occur, the pH may change, and red and white blood cell casts may disintegrate. If it is not possible to examine the urine promptly, it should be refrigerated at 5°C. When appropriate, a collection of urine via suprapubic aspiration may be obtained.

Physical and Gross Examination of Urine

The visual and physical examination of the urine includes an evaluation of color and turbidity.

Color

Typical, normal urine color is pale yellow as a result of the presence of the pigment urochrome. **Urine color varies most commonly because of concentration, but many foods, medications, metabolic products, and infections may produce abnormal urine color.** It is important for the urologist to be aware of the common causes of abnormal urine color, and these are listed in Table 2.1. For example, bright red color or pink suggests blood that may be active bleeding, and purple or brown urine may indicate an old hemorrhage or a retained clot in the bladder. Brown or cola-colored urine can be a sign of glomerular bleeding and disease. Often, the urine color is an important adjunct to the workup and management of the urologic patient.

TABLE 2.1

Common Causes of Abnormal Urine Color

COLOR	CAUSE
Colorless	Very dilute urine
	Overhydration
Cloudy/milky	Phosphaturia
	Pyuria
	Chyluria
Red	Hematuria
	Hemoglobinuria/myoglobinuria
	Anthocyanin in beets and blackberries
	Chronic lead and mercury poisoning
	Phenolphthalein (in bowel evacuants)
	Phenothiazines (e.g., Compazine)
	Rifampin
Orange	Dehydration
	Phenazopyridine (Pyridium)
	Sulfasalazine (Azulfidine)
Yellow	Normal
	Phenacetin
	Riboflavin
Green-blue	Biliverdin
	Indicanuria (tryptophan indole metabolites)
	Amitriptyline (Elavil)
	Indigo carmine
	Methylene blue
	Phenols (e.g., IV cimetidine [Tagamet], IV promethazine [Phenergan])
	Resorcinol
	Triamterene (Dyrenium)
Brown	Urobilinogen
	Porphyria
	Aloe, fava beans, and rhubarb
	Chloroquine and primaquine
	Furazolidone (Furoxone)
	Metronidazole (Flagyl)
	Nitrofurantoin (Furadantin)
Brown-black	Alcaptonuria (homogentisic acid)
	Hemorrhage
	Melanin

	Tyrosinosis (hydroxyphenylpyruvic acid)
	Cascara, senna (laxatives)
	Methocarbamol (Robaxin)
	Methyldopa (Aldomet)
	Sorbitol

IV, Intravenous.

Turbidity

Cloudy urine is commonly caused by phosphaturia, a benign process in which excess phosphate crystals precipitate in alkaline urine. Phosphaturia is often intermittent and may occur after meals, and many patients are otherwise asymptomatic. The diagnosis of phosphaturia can be accomplished either by acidifying the urine with acetic acid, which will result in immediate clearing, or by performing a microscopic analysis, which will reveal large amounts of amorphous phosphate crystals.

Pyuria is another common cause of cloudy urine. The large numbers of white blood cells cause the urine to become turbid. Pyuria is readily distinguished from phosphaturia either by smelling the urine (infected urine has a characteristic pungent odor) or by **urine dipstick or microscopic examination.** The presence of leukocyte esterase or identification of leukocytes on microscopic analysis is diagnostic of pyuria. In patients with indwelling tubes such as catheters or percutaneous nephrostomy tubes, the smell and turbidity of the urine may often be a contributing deciding factor in determining treatment. For example, in a patient with a **long-term indwelling nephrostomy tube and worsening cloudy, smelly urine, the urologist may choose to give both an antibiotic and an antifungal before any manipulation or procedures** while awaiting the results of a urinalysis and culture.

Rare causes of cloudy urine include chyluria (in which there is an abnormal communication between the lymphatic system and the urinary tract resulting in lymph fluid being mixed with urine), lipiduria, hyperoxaluria, and hyperuricosuria.

Chemical Examination of Urine

The chemical examination of the urine involves the assessment of various characteristics of the urine via a urine dipstick. Urine dipsticks provide a quick and inexpensive method for detecting abnormal substances within the urine. Dipsticks are short, plastic strips with small marker pads that are impregnated with different chemical reagents that react with abnormal substances in the urine to produce a colorimetric change. **Dipstick tests include those for specific gravity, pH, blood, protein, glucose, ketones, urobilinogen, leukocyte esterase, and nitrites.**

Substances listed in Table 2.1 that produce an abnormal urine color may interfere with appropriate color development on the dipstick. A common medication that may interfere with the dipstick analysis is phenazopyridine (Pyridium). Phenazopyridine turns the urine bright orange and makes dipstick evaluation of the urine unreliable.

The technique of obtaining an accurate dipstick determination includes completely immersing it in a fresh uncentrifuged urine specimen and then withdrawing it quickly while drawing the edge along the rim of the container to remove excess urine. The dipstick should be held horizontally until the appropriate time for reading and then compared with the color chart. **Excess urine on the dipstick or holding the dipstick in a vertical position will allow mixing of chemicals from adjacent reagent pads on the dipstick, resulting in a faulty diagnosis.** False-negative results for glucose and bilirubin may be seen in the presence of elevated ascorbic acid concentrations in the urine. However, increased levels of ascorbic acid in the urine do not interfere with dipstick testing for hematuria. Highly buffered alkaline urine may cause falsely low readings for specific gravity and may lead to false-negative results for urinary protein. **Other common causes of false results with dipstick testing are outdated test strips and exposure of the sticks**, leading to damage to the reagents. Alterations in the color of the pads before immersing the sticks should be a sign of an outdated or exposed stick.

Specific Gravity and Osmolality

Specific gravity of urine is easily determined from a urinary dipstick and usually varies from 1.001 to 1.035. Specific gravity usually reflects the patient's state of hydration but may also be affected by abnormal renal function, the amount of material dissolved in the urine. A specific gravity less than 1.008 is regarded as dilute, and a specific gravity greater than 1.020 is considered concentrated. Acute or chronic renal insufficiency can be associated with a specific gravity of 1.010.

In general, specific gravity reflects the state of hydration but also affords some idea of renal concentrating ability. Conditions that decrease specific gravity include diuretics, increased fluid intake, diabetes insipidus, and other causes of decreased renal concentrating ability. Conversely, specific gravity can be increased with uncontrolled diabetes mellitus caused by glycosuria, inappropriate secretion of antidiuretic hormone, and any condition causing dehydration. It should be noted that intravenous injection of some iodinated contrasts and administration of dextran can cause a rise in specific gravity above 1.035.

Osmolality is a measure of the amount of material dissolved in the urine and usually varies between 50 and 1200 mOsm/L. Urine osmolality most commonly varies with hydration, and the same factors that affect specific gravity will also affect osmolality. Urine osmolality can be an indicator of renal function, and any abnormal value should be further investigated with additional testing for renal compromise. Furthermore, with alterations in urine osmolality such as very dilute urine (below 308 mOsm), reliable assessment of red blood cells in urine can be compromised due to lysis (Vaughan and Wyker, 1971).

pH

The dipstick test strip incorporates two colorimetric indicators, methyl red and bromothymol blue, which yield clearly distinguishable colors over the pH range from 5 to 9. Urinary pH may vary from 4.5 to 8; the average pH varies between 5.5 and 6.5. A urinary pH between 4.5 and 5.5 is considered acidic, whereas a pH between 6.5 and 8 is considered alkaline.

In general, the urinary pH reflects the pH in the serum. In patients with metabolic or respiratory acidosis, the urine is usually acidic; conversely, in patients with metabolic or respiratory alkalosis, the urine is alkaline. Renal tubular acidosis (RTA) presents an exception to this rule. In patients with both type I and II RTA, the serum is acidemic, but the urine is alkalotic because of continued loss of bicarbonate in the urine. In severe metabolic acidosis in type II RTA, the urine may become acidic, but in type I RTA, the urine is always alkaline, even with severe metabolic acidosis (Morris and Ives, 1991). Urinary pH determination is used to establish the diagnosis of RTA; **inability to acidify the urine below a pH of 5.5 after administration of an acid load is diagnostic of RTA**.

Urine pH determinations are also useful in the diagnosis and treatment of UTIs and urinary calculus disease. **In patients with a presumed UTI, an alkaline urine with a pH greater than 7.5 suggests infection with a urea-splitting organism, most commonly *Proteus*.** Urease-producing bacteria convert ammonia to ammonium ions, markedly elevating the urinary pH and causing precipitation of calcium magnesium ammonium phosphate crystals. Crystallization may result in staghorn calculi.

Urinary pH is usually acidic in patients with uric acid and cystine lithiasis. Alkalinization of the urine is an important feature of therapy in both conditions, and frequent monitoring of urinary pH is necessary to ascertain adequacy of therapy.

Blood/Hematuria

Normal urine should contain less than 3 erythrocytes per HPF. A positive dipstick for blood in the urine indicates either hematuria, hemoglobinuria, or myoglobinuria. **The chemical detection of blood in the urine is based on the peroxidase-like activity of hemoglobin.** When in contact with an organic peroxidase substrate, hemoglobin catalyzes the reaction and causes subsequent oxidation of a chromogen indicator, which changes color according to the degree and amount of oxidation. The degree of color change is directly related to the amount of hemoglobin present in the urine specimen. Dipsticks frequently demonstrate both colored dots and field color change. If present, free hemoglobin and myoglobin in the urine are absorbed into the reagent pad and catalyze the reaction within the test paper, thereby producing a field change effect in color. Intact erythrocytes in the urine undergo hemolysis when they come in contact with the reagent test pad, and the localized free hemoglobin on the pad produces a corresponding dot of color change. The greater the number of intact erythrocytes in the urine specimen, the greater the number of dots that will appear on the test paper, and a coalescence of the dots occurs when there are more than 250 erythrocytes/mL.

Hematuria can be distinguished from hemoglobinuria and myoglobinuria by microscopic examination of the centrifuged urine; the presence of a large

number of erythrocytes establishes the diagnosis of hematuria. If erythrocytes are absent, examination of the serum will distinguish hemoglobinuria and myoglobinuria. A sample of blood is obtained and centrifuged. In hemoglobinuria, the supernatant will be pink. This is because free hemoglobin in the serum binds to haptoglobin, which is water insoluble and has a high molecular weight. This complex remains in the serum, causing a pink color. Free hemoglobin will appear in the urine only when all of the haptoglobin-binding sites have been saturated. In myoglobinuria, the myoglobin released from muscle is of low molecular weight and water soluble. It does not bind to haptoglobin and is therefore excreted immediately into the urine. Therefore in myoglobinuria the serum remains clear.

The sensitivity of urinary dipsticks in identifying microscopic hematuria, defined as greater than or equal to 3 erythrocytes per HPF of centrifuged sediment examined microscopically, is higher than 90%. Conversely, the specificity of the dipstick for hematuria compared with microscopy is somewhat lower, reflecting a higher false-positive rate with the dipstick (Shaw et al., 1985). Things to consider when considering the possibility of a false positive include: contamination of the urine in females when they may be menstruating; significant dehydration, which can result in a higher concentration of erythrocytes; and vigorous exercise, which has been reported to result in clinically significant hematuria (Akiboye and Sharma, 2018). The normal individual excretes about 1000 erythrocytes/mL of urine, with the upper limits of normal varying from 5000 to 8000 erythrocytes/mL (Kincaid-Smith, 1982). Therefore, examining urine of high specific gravity such as the first-void specimen increases the likelihood of a false-positive result.

The efficacy of hematuria screening using the dipstick to identify patients with significant urologic disease is somewhat controversial. Because of the risk for false positives that may lead one to order additional costly and invasive testing, **the dipstick result should be confirmed with a microscopic examination of the centrifuged urinary sediment**. Several societies including the American Urological Association (AUA) have released guidelines (https://www.auanet.org/guidelines/asymptomatic-microhematuria-(2012-reviewed-for-currency-2016) or consensus statements and agree that a urinary dipstick alone is inadequate to confirm the diagnosis of hematuria.

Differential Diagnosis and Evaluation of

Hematuria

One of the early signs and symptoms of nephrologic or urologic disease is microscopic or gross hematuria. Interpreting the microscopic findings of the urinalysis can be helpful in working through the differential diagnosis. Differentiating between nephrologic and urologic causes is critical when deciding what additional tests may need to be ordered. **Identifying the hematuria as nephrologic versus urologic and glomerular versus nonglomerular is one of the first steps in the analysis.**

Hematuria of nephrologic origin is frequently associated with casts in the urine and almost always associated with significant proteinuria. Significant gross hematuria of urologic origin is unlikely to elevate the protein concentration in the urine into the 100 to 300 mg/dL or 2+ to 3+ range on dipstick, and proteinuria of this magnitude almost always indicates glomerular or tubulointerstitial renal disease prompting a consultation with nephrology. Morphologic evaluation of erythrocytes in the centrifuged urinary sediment also helps localize their site of origin. **Erythrocytes arising from glomerular disease are typically dysmorphic and show a wide range of morphologic alterations. Conversely, erythrocytes arising from tubulointerstitial renal disease and of urologic origin have a uniformly round shape;** these erythrocytes may or may not retain their hemoglobin (“ghost cells”), but the individual cell shape is consistently round.

Glomerular Hematuria

Glomerular hematuria is suggested by the presence of dysmorphic erythrocytes, RBC casts, proteinuria, and brown or cola-colored urine. Of those patients with glomerulonephritis proven by renal biopsy, however, about 20% will have hematuria alone without RBC casts or proteinuria (Fassett et al., 1982).

The glomerular disorders associated with hematuria are listed in Table 2.2. Further evaluation of patients with glomerular hematuria should begin with a thorough history and possibly a consultation with nephrology. Hematuria in children and young adults, usually males, associated with low-grade fever and an erythematous rash suggests a diagnosis of immunoglobulin A (IgA) nephropathy (Berger disease). A family history of renal disease and deafness suggests familial nephritis or Alport syndrome. Hemoptysis and abnormal bleeding associated with microcytic anemia are characteristic of Goodpasture syndrome, and the presence of a rash and arthritis suggest systemic lupus erythematosus. Finally, poststreptococcal glomerulonephritis should be suspected in a child with a recent streptococcal upper respiratory tract or skin infection.

TABLE 2.2

Glomerular Disorders in Patients With Glomerular Hematuria

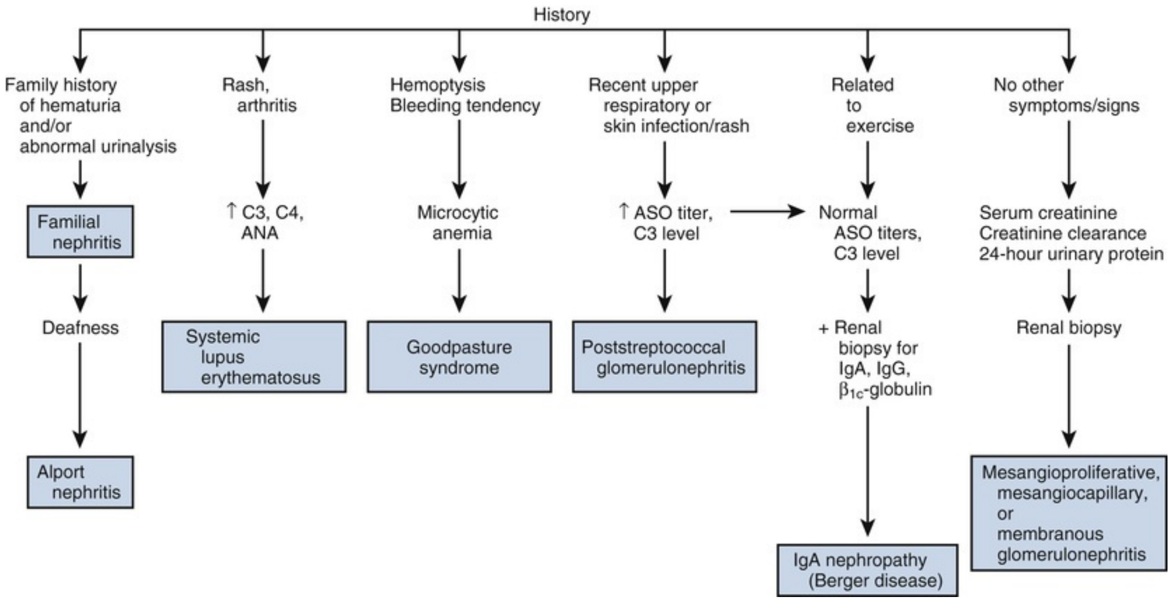
DISORDER	PATIENTS
IgA nephropathy (Berger disease)	30
Mesangioproliferative GN	14
Focal segmental proliferative GN	13
Familial nephritis (e.g., Alport syndrome)	11
Membranous GN	7
Mesangiocapillary GN	6
Focal segmental sclerosis	4
Unclassifiable	4
Systemic lupus erythematosus	3
Postinfectious GN	2
Subacute bacterial endocarditis	2
Others	4
Total	100

GN, Glomerulonephritis; *IgA,* immunoglobulin A.

Modified from Fassett RG, Horgan BA, Mathew TH. Detection of glomerular bleeding by phase-contrast microscopy. *Lancet.* 1982;1(8287):1432–1434.

Further laboratory evaluation often includes measurement of serum creatinine, creatinine clearance, and a 24-hour urine protein determination. Although these tests will quantitate the specific degree of renal dysfunction, further tests are usually required to establish the specific diagnosis and particularly to determine whether the disease is caused by an immune or a nonimmune etiology. **Frequently, a renal biopsy is necessary to establish the precise diagnosis, and biopsies are particularly important if the result will influence subsequent treatment of the patient.** Renal biopsies are extremely informative when examined by an experienced pathologist using light, immunofluorescence, and electron microscopy.

An algorithm for the evaluation of glomerular hematuria is shown in Fig. 2.1.



History
Family history of hematuria and/or abnormal urinalysis
Familial nephritis
Deafness
Alport nephritis
Rash, arthritis
↑ C3, C4, ANA
Systemic lupus erythematosus
Hemoptysis Bleeding tendency
Microcytic anemia
Goodpasture syndrome
Recent upper respiratory or skin infection/rash
↑ ASO titer, C3 level
Poststreptococcal glomerulonephritis
Related to exercise
Normal ASO titers, C3 level
+ Renal biopsy for IgA, IgG, β1c-globulin
IgA nephropathy (Berger disease)
No other symptoms/signs
Serum creatinine Creatinine clearance 24-hour urinary protein
Renal biopsy
Mesangioproliferative, mesangiocapillary, or membranous glomerulonephritis

FIG. 2.1 Evaluation of glomerular hematuria (dysmorphic erythrocytes, erythrocyte casts, and proteinuria). *ANA,* Antinuclear antibody; *ASO,* antistreptolysin O; *Ig,* immunoglobulin.

IgA Nephropathy (Berger Disease)

IgA nephropathy, or Berger disease, is the most common cause of glomerular hematuria, accounting for about 30% of cases (Fassett et al., 1982). Therefore it is described in greater detail in this section. IgA nephropathy occurs most commonly in children and young adults, with a male predominance (Berger and Hinglais, 1968). Patients typically present with hematuria after an upper respiratory tract infection or exercise. Hematuria may be associated with a low-grade fever or rash, but most patients have no associated systemic symptoms. Gross hematuria occurs intermittently, but microscopic hematuria is a constant finding in some patients. The disease is chronic, but the prognosis in most patients is excellent. Renal function remains normal in the majority, but about 25% will subsequently develop renal insufficiency. Older age at onset, initial abnormal renal function, consistent proteinuria, and hypertension are indicators of a poor prognosis (D'Amico, 1988).

The pathologic findings in Berger disease are limited to either focal glomeruli or lobular segments of a glomerulus. The changes are proliferative and usually confined to mesangial cells (Berger and Hinglais, 1968). Renal biopsy reveals deposits of IgA, IgG, and β_{1c}-globulin, although IgA and IgG mesangial deposits are found in other forms of glomerulonephritis as well. The role of IgA in the disease remains uncertain, although the deposits may trigger an inflammatory reaction within the glomerulus (van den Wall Bake et al, 1989). Because gross hematuria frequently follows an upper respiratory tract infection, a viral etiology has been suspected but not established. The frequent association between hematuria and exercise in this condition remains unexplained.

The clinical presentation of IgA glomerulonephritis is alarming and similar to certain systemic diseases, including Schönlein-Henoch purpura, systemic lupus erythematosus, bacterial endocarditis, and Goodpasture syndrome. Therefore a careful clinical and laboratory evaluation is indicated to establish the correct diagnosis. The presence of RBC casts establishes the glomerular origin of the hematuria. In the absence of casts, a urologic evaluation is indicated to exclude the urinary tract as a source of bleeding and to confirm that the hematuria is arising from both kidneys. The diagnosis of IgA nephropathy is confirmed by renal biopsy demonstrating the classic deposits of immunoglobulins in mesangial cells, as described earlier in this chapter. Once the diagnosis has been established, repeat evaluations for hematuria are generally not indicated. Although there is no effective treatment for this condition, renal function remains stable in most patients, and there are no other known long-term complications.

Nonglomerular Hematuria

Medical/Nonsurgical

Medical causes of nonglomerular hematuria of renal origin are secondary to either tubulointerstitial, renovascular, or systemic disorders. **The urinalysis in nonglomerular hematuria is distinguished from that of glomerular hematuria by the presence of circular erythrocytes and the absence of erythrocyte casts.** It is frequently associated with significant proteinuria, which distinguishes these nephrologic diseases from urologic diseases in which the degree of proteinuria is usually minimal, even with heavy bleeding.

As with glomerular hematuria, a careful history frequently helps establish the diagnosis. A family history of hematuria or bleeding tendency suggests the diagnosis of a blood dyscrasia, which should be investigated further. A family history of urolithiasis associated with intermittent hematuria may indicate inherited stone disease, which should be investigated with serum and urine measurements of calcium and uric acid. A family history of renal cystic disease should prompt further radiologic evaluation for medullary sponge kidney and adult polycystic kidney disease. **Papillary necrosis as a cause of hematuria should be considered in diabetics, African-Americans (secondary to sickle cell disease or trait), and suspected analgesic abusers.**

Medications may induce hematuria, particularly anticoagulants. **Anticoagulation at normal therapeutic levels, however, does not predispose patients to hematuria.** In one study, the prevalence of hematuria was 3.2% in anticoagulated patients versus 4.8% in a control group. Urologic disease was identified in 81% of patients with more than one episode of microscopic hematuria, and the cause of hematuria did not vary between groups (Culclasure et al., 1994). Thus anticoagulant therapy per se does not appear to increase the risk for hematuria unless the patient is excessively anticoagulated. Therefore, in patients on anticoagulation, hematuria should not be attributed to the medication, and a proper thorough workup should be performed as it would in any other patient that is not anticoagulated.

Exercise-induced hematuria can be observed in patients with a recent history of vigorous exercise such as extreme or long-distance running (Akiboye and Sharma, 2018). In long-distance runners (>10 km), it is usually noted at the conclusion of the run, and rapidly disappears with rest. The hematuria may be of renal or bladder origin. An increased number of dysmorphic erythrocytes have been noted in some patients, suggesting a glomerular origin. Exercise-induced hematuria may be the first sign of underlying glomerular disease such as IgA nephropathy. Conversely, cystoscopy in patients with exercise-induced hematuria frequently reveals punctate hemorrhagic lesions in the bladder, suggesting that the hematuria is of bladder origin.

Vascular disease may also result in nonglomerular hematuria. Renal artery embolism and thrombosis, arteriovenous fistulae, and renal vein thrombosis may all result in hematuria. Physical examination may reveal severe hypertension, a flank or abdominal bruit, or atrial fibrillation. In such patients, further evaluation for renal vascular disease should be undertaken. Microscopic hematuria has also been reported in Nutcracker syndrome associated with pelvic congestion (Chau et al., 2018; Gulleroglu et al., 2014).

Surgical

Nonglomerular hematuria caused by surgical and urologic causes includes pathology of the collecting system of the urinary tract. Common causes include urologic tumors, stones, benign prostatic hyperplasia, and urinary tract infections.

The urinalysis in both nonglomerular medical and surgical hematuria is similar in that both are characterized by circular erythrocytes and the absence of erythrocyte casts. Essential hematuria is suggested, however, by the absence of significant proteinuria usually found in nonglomerular hematuria of renal parenchymal origin. It should be remembered, however, that proteinuria is not always present in glomerular or nonglomerular renal disease.

Asymptomatic microscopic hematuria (AMH) "is defined as three or greater RBC/HPF on a properly collected urinary specimen in the absence of an obvious benign cause" (Davis et al., 2012, reviewed and validated 2016). The AUA guideline on the diagnosis, evaluation, and follow-up of AMH in adults provides 19 guideline statements and an algorithm for AMH (https://www.auanet.org/guidelines/asymptomatic-microhematuria-(2012-reviewed-for-currency-2016)).

Proteinuria

Healthy adults excrete 80 to 150 mg of protein in the urine daily. The qualitative detection of proteinuria in the urinalysis should raise the suspicion of underlying renal disease. **Proteinuria may be the first indication of renovascular, glomerular, or tubulointerstitial renal disease, or it may represent the overflow of abnormal proteins into the urine in conditions such as multiple myeloma.** Proteinuria can also occur secondary to nonrenal disorders and in response to various physiologic conditions such as strenuous exercise.

The protein concentration in the urine depends on the state of hydration, but it seldom exceeds 20 mg/dL. In patients with dilute urine, however, significant proteinuria may be present at concentrations less than 20 mg/dL. **Normally, urine protein is about 30% albumin, 30% serum globulins, and 40% tissue proteins, of which the major component is Tamm-Horsfall protein.** This profile may be altered by conditions that affect glomerular filtration, tubular reabsorption, or excretion of urine protein. Determination of the urine protein profile by such techniques as protein electrophoresis may help determine the etiology of proteinuria.

Pathophysiology

Most causes of proteinuria can be categorized into one of three categories: glomerular, tubular, or overflow. Glomerular proteinuria is the most common type of proteinuria and results from increased glomerular

capillary permeability to protein, especially albumin. Glomerular proteinuria occurs in any of the primary glomerular diseases such as IgA nephropathy or in glomerulopathy associated with systemic illness such as diabetes mellitus. Glomerular disease should be suspected when the 24-hour urine protein excretion exceeds 1 g and is almost certain to exist when the total protein excretion exceeds 3 g.

Tubular proteinuria results from failure to reabsorb normally filtered proteins of low molecular weight such as immunoglobulins. In tubular proteinuria, the 24-hour urine protein loss seldom exceeds 2 to 3 g, and the excreted proteins are of low molecular weight rather than albumin. Disorders that lead to tubular proteinuria are commonly associated with other defects of proximal tubular function such as glycosuria, aminoaciduria, phosphaturia, and uricosuria (Fanconi syndrome).

Overflow proteinuria occurs in the absence of any underlying renal disease and is caused by an increased plasma concentration of abnormal immunoglobulins and other low–molecular-weight proteins. The increased serum levels of abnormal proteins result in excess glomerular filtration that exceeds tubular reabsorptive capacity. The most common cause of overflow proteinuria is multiple myeloma, in which large amounts of immunoglobulin light chains are produced and appear in the urine (Bence Jones protein).

Detection

Qualitative detection of abnormal proteinuria is most easily accomplished with a dipstick impregnated with tetrabromophenol blue dye. The color of the dye changes in response to a pH shift related to the protein content of the urine, mainly albumin, leading to the development of a blue color. Because the background of the dipstick is yellow, various shades of green will develop, and the darker the green, the greater the concentration of protein in the urine. The minimal detectable protein concentration by this method is 20 to 30 mg/dL. **False-negative results can occur in alkaline urine, dilute urine, or when the primary protein present is not albumin.** Nephrotic range proteinuria in excess of 1 g/24 h, however, is seldom missed on qualitative screening. Precipitation of urinary proteins with strong acids such as 3% sulfosalicylic acid will detect proteinuria at concentrations as low as 15 mg/dL and is more sensitive at detecting other proteins and albumin. Patients whose urine is negative on dipstick but strongly positive with sulfosalicylic acid should be suspected of having multiple myeloma, and the urine should be tested further for Bence Jones protein.

If qualitative testing reveals proteinuria, this should be quantitated with a 24-hour urinary collection. Further qualitative assessment of abnormal urinary proteins can be accomplished by either protein electrophoresis or immunoassay for specific proteins. **Protein electrophoresis is particularly helpful in distinguishing glomerular from tubular proteinuria. In glomerular proteinuria, albumin makes up about 70% of the total protein excreted, whereas in tubular proteinuria, the major proteins excreted are immunoglobulins, with albumin making up only 10% to 20%. Immunoassay is the method of choice for detecting specific proteins such as Bence Jones protein in multiple myeloma.**

Evaluation

Proteinuria should first be classified by its timing into transient, intermittent, or persistent. Transient proteinuria occurs commonly, especially in the pediatric population, and usually resolves spontaneously within a few days (Wagner et al., 1968). It may result from fever, exercise, or emotional stress. In older patients, transient proteinuria may be caused by congestive heart failure. If a nonrenal cause is identified and a subsequent urinalysis is negative, no further evaluation is necessary. If proteinuria persists, it should be evaluated further.

Proteinuria may also occur intermittently, and this is frequently related to postural change (Robinson, 1985). Proteinuria that occurs only in the upright position is a frequent cause of mild, intermittent proteinuria in young males. Total daily protein excretion seldom exceeds 1 g, and urinary protein excretion returns to normal when the patient is recumbent. Orthostatic proteinuria is thought to be secondary to increased pressure on the renal vein while standing. It resolves spontaneously in about 50% of patients and is not associated with morbidity. Therefore if renal function is normal in patients with orthostatic proteinuria, no further evaluation is indicated.

Persistent proteinuria requires further evaluation, and most cases have a glomerular etiology. A quantitative measurement of urinary protein should be obtained through a 24-hour urine collection, and a qualitative evaluation should be obtained to determine the major proteins excreted. The findings of greater than 2 g of protein excreted per 24 hours, of which the major components are high-molecular-weight proteins such as albumin, establish the diagnosis of glomerular proteinuria. Glomerular proteinuria is the most common cause of abnormal proteinuria, especially in patients presenting with persistent proteinuria. If glomerular proteinuria is associated with hematuria characterized by dysmorphic erythrocytes and erythrocyte casts, the patient should be evaluated as outlined earlier for glomerular hematuria (see Fig. 2.1). Patients with glomerular proteinuria who have no or little associated hematuria should be evaluated for other conditions, of which the most common is diabetes mellitus. Other possibilities include amyloidosis and arteriolar nephrosclerosis.

In patients in whom total protein excretion is 300 to 2000 mg/day, of which the major components are low–molecular-weight globulins, further qualitative evaluation with immunoelectrophoresis is indicated. This will determine whether the excess proteins are normal or abnormal. Identification of normal proteins establishes a diagnosis of tubular proteinuria, and further evaluation for a specific cause of tubular dysfunction is indicated.

If qualitative evaluation reveals abnormal proteins in the urine, this establishes a diagnosis of overflow proteinuria. Further evaluation should be directed to identify the specific protein abnormality. The finding of large quantities of light-chain immunoglobulins or Bence Jones protein establishes a diagnosis of multiple myeloma. Similarly, the finding of large amounts of hemoglobin or myoglobin establishes the diagnosis of hemoglobinuria or myoglobinuria. An algorithm for the evaluation of proteinuria is shown in Fig. 2.2.

FIG. 2.2 Evaluation of proteinuria.

Glucose and Ketones

Urine testing for glucose and ketones is useful in screening patients for diabetes mellitus. Normally, almost all of the glucose filtered by the glomeruli is reabsorbed in the proximal tubules. Although small amounts of glucose may normally be excreted in the urine, these amounts are not clinically significant and are below the level of detectability with the dipstick. If, however, the amount of glucose filtered exceeds the capacity of tubular reabsorption, glucose will be excreted in the urine and detected on the dipstick. **This so-called *renal threshold* corresponds to serum glucose of about 180 mg/dL; above this level, glucose will be detected in the urine.**

Glucose detection with the urinary dipstick is based on a double sequential enzymatic reaction yielding a colorimetric change. In the first reaction, glucose in the urine reacts with glucose oxidase on the dipstick to form gluconic acid and hydrogen peroxide. In the second reaction, hydrogen peroxide reacts with peroxidase, causing oxidation of the chromogen on the dipstick, producing a color change. **This double-oxidative reaction is specific for glucose, and there is no cross-reactivity with other sugars.** The dipstick test becomes less sensitive as the urine increases in specific gravity and temperature.

Ketones are not normally found in the urine but will appear when the carbohydrate supplies in the body are depleted and body fat breakdown occurs. This happens most commonly in diabetic ketoacidosis but may also occur during pregnancy and after periods of starvation or rapid weight reduction. **Ketones excreted include acetoacetic acid, acetone, and β-hydroxybutyric acid. With abnormal fat breakdown, ketones will appear in the urine before the serum.**

Dipstick testing for ketones involves a colorimetric reaction: Sodium nitroprusside on the dipstick reacts with acetoacetic acid to produce a purple color. **Dipstick testing will identify acetoacetic acid at concentrations of 5 to 10 mg/dL but will not detect acetone or β-hydroxybutyric acid.** A dipstick that tests positive for glucose should also be tested for ketones, and diabetes mellitus is suggested. False-positive results, however, can occur in acidic urine of high specific gravity, in abnormally colored urine, and in urine containing levodopa metabolites, 2-mercaptoethane sulfonate sodium, and other sulfhydryl-containing compounds (Csako, 1987).

Bilirubin and Urobilinogen

Normal urine contains no bilirubin and only small amounts of urobilinogen. There are two types of bilirubin: direct (conjugated) and indirect. Direct bilirubin is made in the hepatocyte, where bilirubin is conjugated with glucuronic acid. **Conjugated bilirubin has a low molecular weight, is water soluble, and normally passes from the liver to the small intestine through the bile ducts, where it is converted to urobilinogen. Therefore conjugated bilirubin does not appear in the urine except in pathologic conditions in which there is intrinsic hepatic disease or obstruction of the bile ducts.**

Indirect bilirubin is of high molecular weight and bound in the serum to albumin. It is water insoluble and therefore does not appear in the urine, even in pathologic conditions.

Urobilinogen is the end product of conjugated bilirubin metabolism. Conjugated bilirubin passes through the bile ducts, where it is metabolized by normal intestinal bacteria to urobilinogen. Normally, about 50% of the urobilinogen is excreted in the stool, and 50% is reabsorbed into the enterohepatic circulation. A small amount of absorbed urobilinogen, about 1 to 4 mg/day, will escape hepatic uptake and be excreted in the urine. Hemolysis and hepatocellular diseases that lead to increased bile pigments can result in increased urinary urobilinogen. Conversely, obstruction of the bile duct or antibiotic usage that alters intestinal flora, thereby interfering with the conversion of conjugated bilirubin to urobilinogen, will decrease urobilinogen levels in the urine. In these conditions, serum levels of conjugated bilirubin rise.

There are different dipstick reagents and methods to test for both bilirubin and urobilinogen, but the basic physiologic principle involves the binding of bilirubin or urobilinogen to a diazonium salt to produce a colorimetric reaction. False-negative results can occur in the presence of ascorbic acid, which decreases the sensitivity for detection of bilirubin. False-positive results can occur in the presence of phenazopyridine because it colors the urine orange and, similar to the colorimetric reaction for bilirubin, turns red in an acid medium.

Leukocyte Esterase and Nitrite Tests

Leukocyte esterase activity indicates the presence of white blood cells in the urine. The presence of nitrites in the urine is strongly suggestive of bacteriuria. Thus both tests have been used to screen patients for UTIs. The most accurate method to diagnose infection is by microscopic examination of the urinary sediment to identify pyuria and subsequent urine culture**. If the dipstick is positive for leukocyte esterase but negative for nitrites, noninfectious causes of inflammation should be considered and a microscopic analysis and urine culture should be obtained before any empirical antibiotic therapy should be prescribed.**

Leukocyte esterase is produced by neutrophils and catalyzes the hydrolysis of an indoxyl carbonic acid ester to indoxyl (Gillenwater, 1981). The indoxyl formed oxidizes a diazonium salt chromogen on the dipstick to produce a color change. It is recommended that leukocyte esterase testing be done 5 minutes after the dipstick is immersed in the urine to allow adequate incubation (Shaw et al., 1985). The sensitivity of this test subsequently decreases with time because of lysis of the leukocytes. Leukocyte esterase testing may also be negative in the presence of infection because not all patients with bacteriuria will have significant pyuria. Therefore if one uses leukocyte esterase testing to screen patients for UTI, it should always be done in conjunction with nitrite testing for bacteriuria (Pels et al, 1989).

Other causes of false-negative results with leukocyte esterase testing include increased urinary specific gravity, glycosuria, presence of urobilinogen, medications that alter urine color, and ingestion of large amounts of ascorbic acid. **The major cause of false-positive leukocyte esterase tests is specimen**

contamination.

Nitrites are not normally found in the urine, but many species of gram-negative bacteria can convert nitrates to nitrites. Nitrites are readily detected in the urine because they react with the reagents on the dipstick and undergo diazotization to form a red azo dye. The specificity of the nitrite dipstick for detecting bacteriuria is higher than 90% (Pels et al., 1989). The sensitivity of the test, however, is considerably less, varying from 35% to 85%. The nitrite test is less accurate in urine specimens containing fewer than 10^5 organisms/mL (Kellogg et al., 1987). As with leukocyte esterase testing, the major cause of false-positive nitrite testing is contamination.

A protocol combining the visual appearance of the urine with leukocyte esterase and nitrite testing has been proposed when in-office microscopy is not available (Fig. 2.3). It reportedly detects 95% of infected urine specimens and decreases the need for microscopy by as much as 30% (Flanagan et al., 1989). Other studies, however, have shown that dipstick testing is not an adequate replacement for microscopy (Propp et al., 1989). As stated earlier, any dipstick test that is positive for only one without the other should be confirmed with microscopy and culture before prescribing any treatment. In summary, it has not been demonstrated conclusively that dipstick testing for UTI can replace microscopic examination of the urinary sediment.

FIG. 2.3 Protocol for determining the need for urine sediment microscopy in an asymptomatic population. (From Flanagan PG, Rooney PG, Davies EA, et al. Evaluation of four screening tests for bacteriuria in elderly people. *Lancet.* 1989;1(8647):1117–1119. © by The Lancet Ltd., 1989.)

Urinary Sediment

Obtaining and Preparing the Specimen

A clean-catch midstream urine specimen should be obtained. As described earlier, uncircumcised men should retract the prepuce and cleanse the glans penis before voiding. It is more difficult to obtain a reliable clean-catch specimen in females because of contamination with introital leukocytes and bacteria. **If there is any suspicion of a UTI in a female, a catheterized urine sample should be obtained for culture and sensitivity**.

If possible, **the first-void urine specimen is the specimen of choice and should be examined within 1 hour.** A standard procedure for preparation of the urine for microscopic examination has been described (Cushner and Copley, 1989). Ten to 15 milliliters of urine should be centrifuged for 5 minutes at 3000 rpm. The supernatant is then poured off, and the sediment is resuspended with 0.3 mL of saline in the centrifuge tube by gently tapping the bottom of the tube. Although the remaining small amount of fluid can be poured onto a microscope slide, this usually results in excess fluid on the slide. It is better to use a small pipette to withdraw the residual fluid from the centrifuge tube and to place it directly on the microscope slide. This usually results in an ideal volume of between 0.01 and 0.02 mL of fluid deposited on the slide. The slide is then covered with a coverslip. The edge of the coverslip should be placed on the slide first to allow the drop of fluid to ascend onto the coverslip by capillary action. The coverslip is then gently placed over the drop of fluid, and this technique allows for most of the air between the drop of fluid and the coverslip to be expelled. If one simply drops the coverslip over the urine, the urine will disperse over the slide and there will be a considerable number of air bubbles that may distort the subsequent microscopic examination.

Microscopy Technique

Microscopic analysis of urinary sediment should be performed with both low-power (×100 magnification) and high-power (×400 magnification) lenses. At least 10 to 20 microscopic fields should be analyzed. The use of an oil immersion lens for higher magnification is seldom, if ever, necessary. Under low power, the entire area under the coverslip should be scanned. **Particular attention should be given to the edges of the coverslip, where casts and other elements tend to be concentrated.** Low-power magnification is sufficient to identify erythrocytes, leukocytes, casts, cystine crystals, oval fat macrophages, and parasites such as *Trichomonas vaginalis* and *Schistosoma hematobium*.

High-power magnification is necessary to distinguish circular from dysmorphic erythrocytes, to identify other types of crystals, and, particularly, to identify bacteria and yeast. In summary, **the urinary sediment should be examined microscopically for (1) cells, (2) casts, (3) crystals, (4) bacteria, (5) yeast, and (6) parasites.**

Cells

Erythrocyte morphology may be determined under high-power magnification. Although phase contrast microscopy has been used for this purpose, circular (nonglomerular) erythrocytes can generally be distinguished from dysmorphic (glomerular) erythrocytes under routine brightfield high-power magnification (Figs. 2.4 to 2.8). **This is assisted by adjusting the microscope condenser to its lowest aperture, thus reducing the intensity of background light. This**

allows one to see fine detail not evident otherwise and also creates the effect of phase microscopy because cell membranes and other sedimentary components stand out against the darkened background.

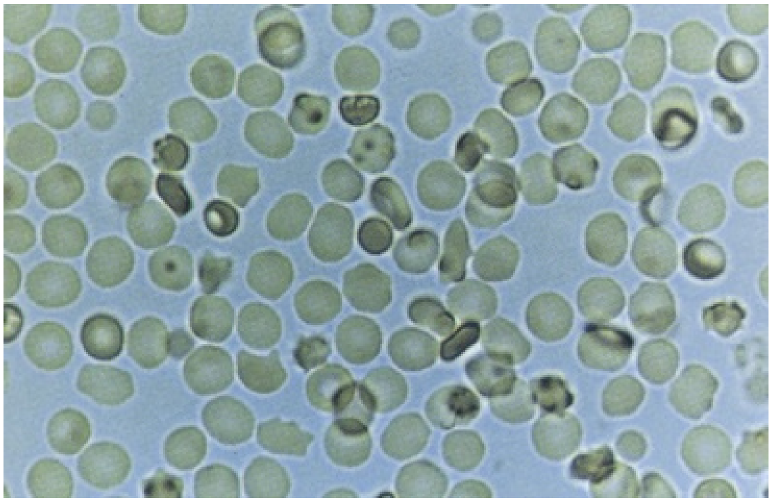

FIG. 2.4 Red blood cells, both smoothly rounded and mildly crenated, typical of epithelial erythrocytes.

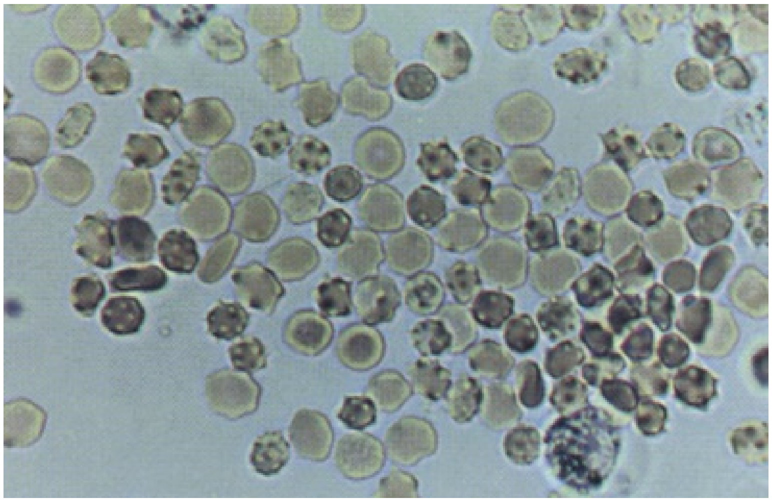

FIG. 2.5 Red blood cells from a patient with a bladder tumor.

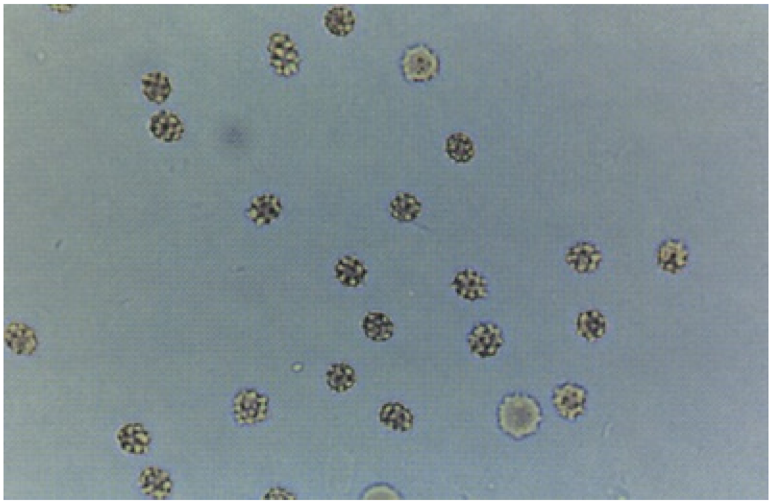

FIG. 2.6 Red blood cells from a patient with interstitial cystitis. Cells were collected at cystoscopy.

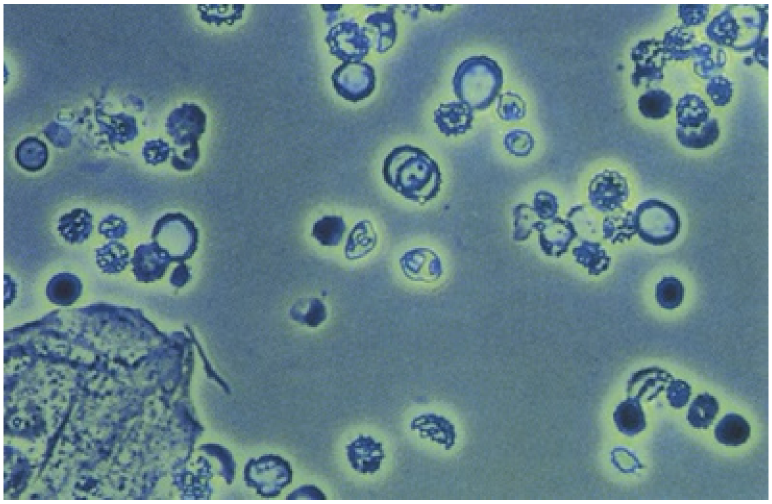

FIG. 2.7 Red blood cells from a patient with Berger disease. Note variations in membranes characteristic of dysmorphic red blood cells.

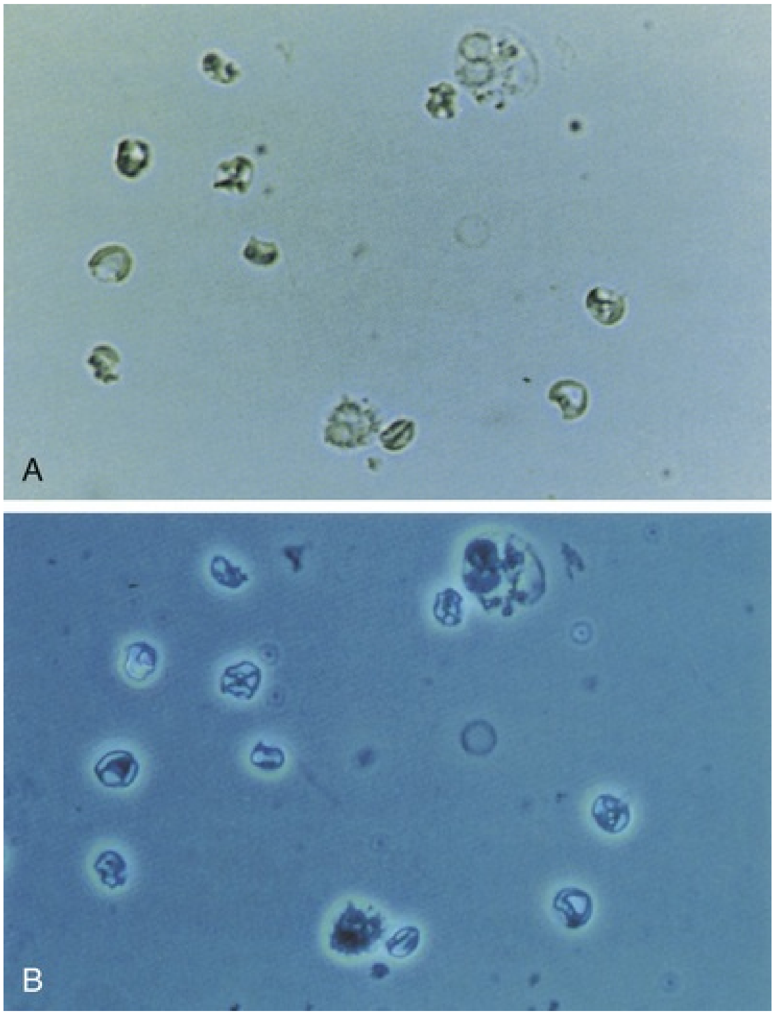

FIG. 2.8 Dysmorphic red blood cells from a patient with Wegener granulomatosis. (A) Brightfield illumination. (B) Phase illumination. Note irregular deposits of dense cytoplasmic material around the cell membrane.

Circular erythrocytes generally have an even distribution of hemoglobin with either a round or crenated contour, whereas dysmorphic erythrocytes are irregularly shaped with minimal hemoglobin and irregular distribution of cytoplasm. Automated techniques for performing microscopic analysis to distinguish the two types of erythrocytes have been investigated but have not yet been accepted into general urologic practice and are probably unnecessary. In one study using a standard Coulter counter, microscopic analysis was found to be 97% accurate in differentiating between the two types of erythrocytes (Sayer et al., 1990). **Erythrocytes may be confused with yeast or fat droplets** (Fig. 2.9). Erythrocytes can be distinguished, however, because yeast will show budding, and oil droplets are highly refractile.

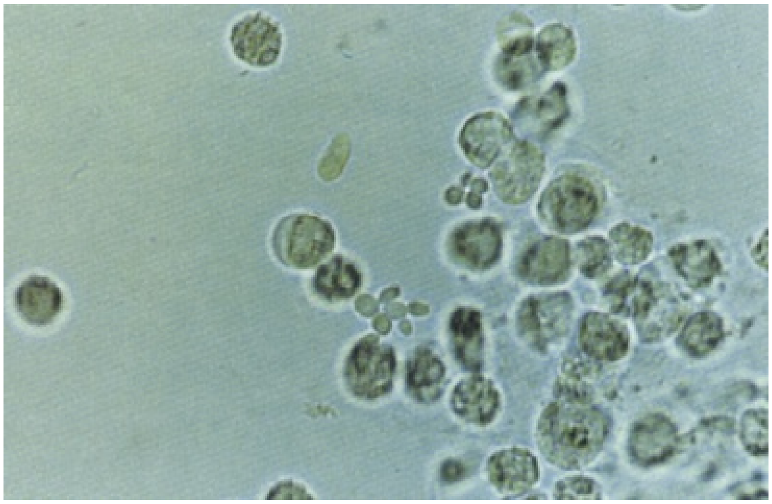

FIG. 2.9 *Candida albicans.* Budding forms surrounded by leukocytes.

Leukocytes can generally be identified under low-power magnification and definitively diagnosed under high-power magnification (Figs. 2.10 and 2.11; see Fig. 2.9). It is normal to find 1 or 2 leukocytes per HPF in men and up to 5 per HPF in women in whom the urine sample may be contaminated with vaginal secretions. A greater number of leukocytes generally indicates infection or inflammation in the urinary tract. It may be possible to distinguish **old leukocytes, which have a characteristic small and wrinkled appearance** and which are commonly found in the vaginal secretions of normal women, from fresh leukocytes, which are generally indicative of urinary tract pathology. Fresh leukocytes are generally larger and rounder, and, when the specific gravity is less than 1.019, the granules in the cytoplasm demonstrate glitterlike movement, so-called *glitter cells.*

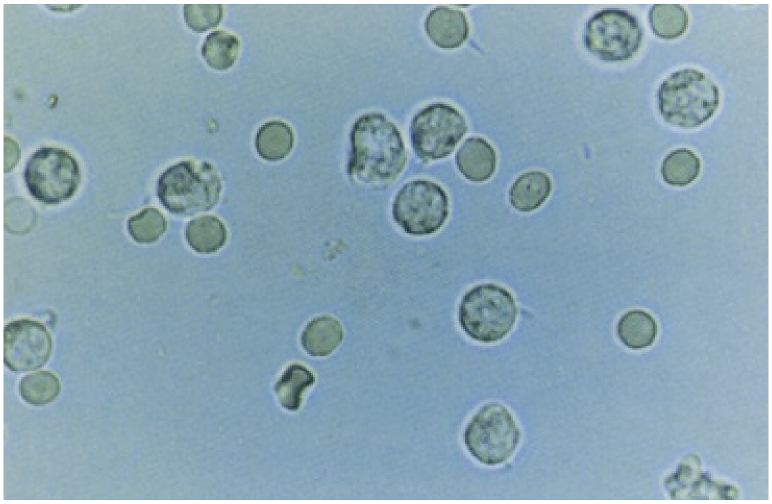

FIG. 2.10 Old leukocytes. Staghorn calculi with Proteus infection.

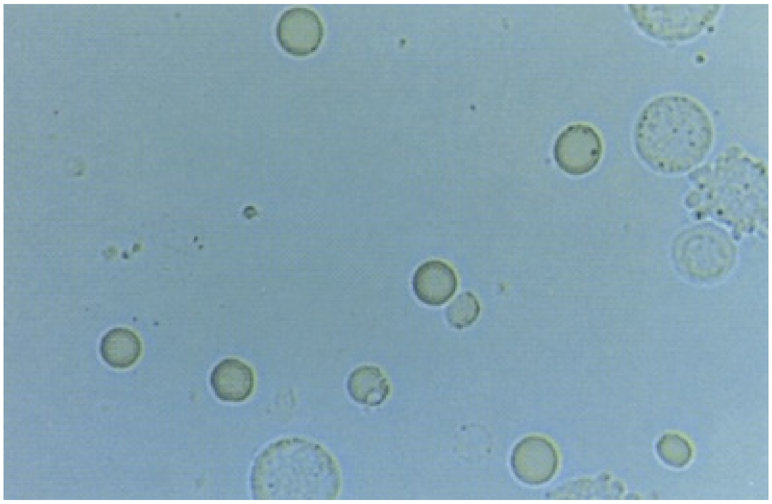

FIG. 2.11 Fresh “glitter cells” with erythrocytes in background.

Epithelial cells are commonly observed in the urinary sediment. Squamous cells are frequently detected in female urine specimens and are derived from the lower portion of the urethra, the trigone of postpubertal females, and the vagina. **Squamous epithelial cells are large, have a central small nucleus about the size of an erythrocyte, and have an irregular cytoplasm with fine granularity.** Transitional epithelial cells may arise from the remainder of the urinary tract (Fig. 2.12). Transitional cells are smaller than squamous cells, have a larger nucleus, and demonstrate prominent cytoplasmic granules near the nucleus. Malignant transitional cells have altered nuclear size and morphology and can be identified with either routine Papanicolaou staining or automated flow cytometry.

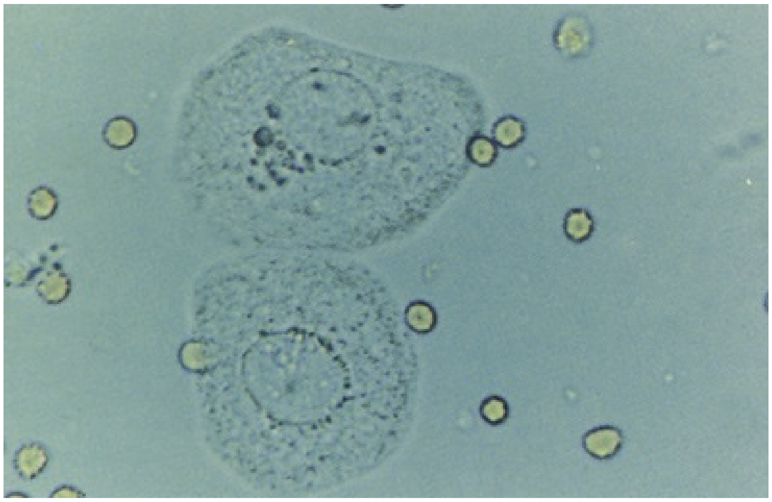

FIG. 2.12 Transitional epithelial cells from bladder lavage.

Renal tubular cells are the least commonly observed epithelial cells in the urine but are most significant because their presence in the urine is always indicative of renal pathology. Renal tubular cells may be difficult to distinguish from leukocytes, but they are slightly larger.

Casts

A cast is a protein coagulum that is formed in the renal tubule and traps any tubular luminal contents within the matrix. **Tamm-Horsfall mucoprotein is the basic matrix of all renal casts; it originates from tubular epithelial cells and is always present in the urine.** When the casts contain only mucoproteins, they are called *hyaline casts* and may not have any pathologic significance. Hyaline casts may be seen in the urine after exercise or heat exposure but may also be observed in pyelonephritis or chronic renal disease.

RBC casts contain entrapped erythrocytes and are diagnostic of glomerular bleeding, most likely secondary to glomerulonephritis (Figs. 2.13 and 2.14). White blood cell casts are observed in acute glomerulonephritis, acute pyelonephritis, and acute tubulointerstitial nephritis. Casts with other cellular elements, usually sloughed renal tubular epithelial cells, are indicative of nonspecific renal damage (Fig. 2.15). Granular and waxy casts result from further degeneration of cellular elements. Fatty casts are seen in nephrotic syndrome, lipiduria, and hypothyroidism.

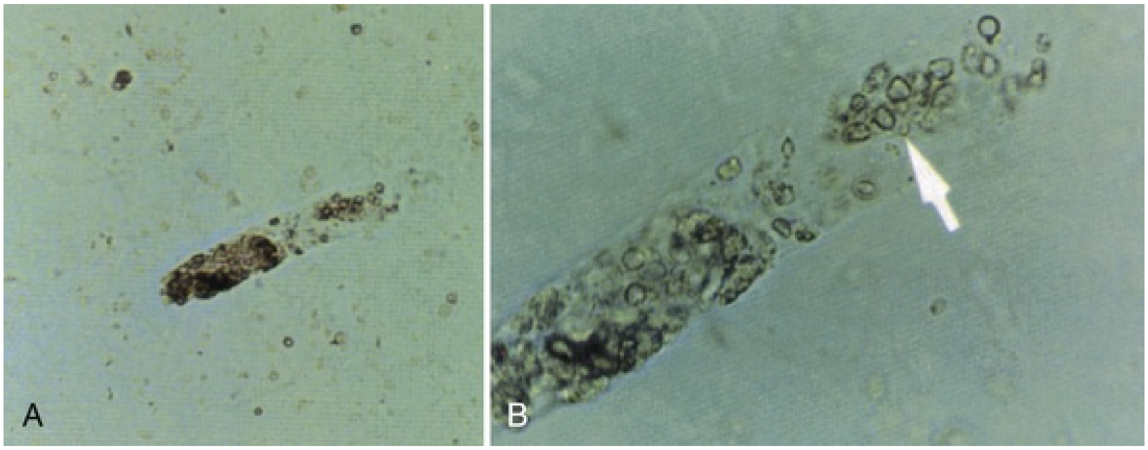

FIG. 2.13 Red blood cell cast. (A) Low-power view demonstrates distinct border of hyaline matrix. (B) High-power view demonstrates the sharply defined red blood cell membranes *(arrow).*

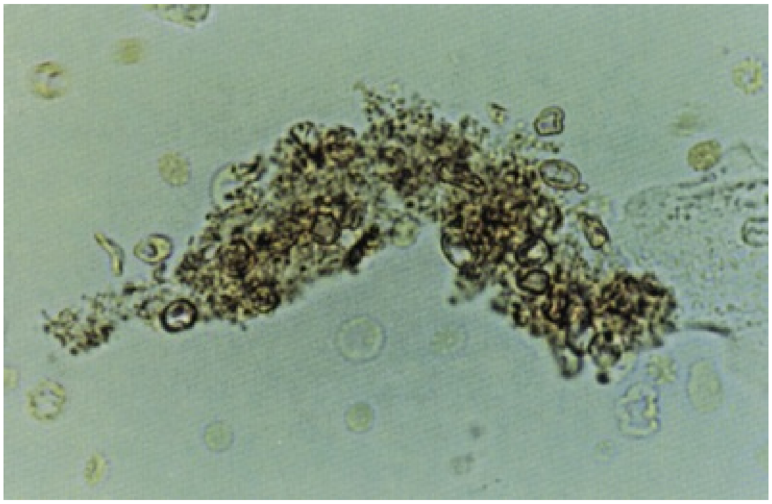

FIG. 2.14 Red blood cell cast.

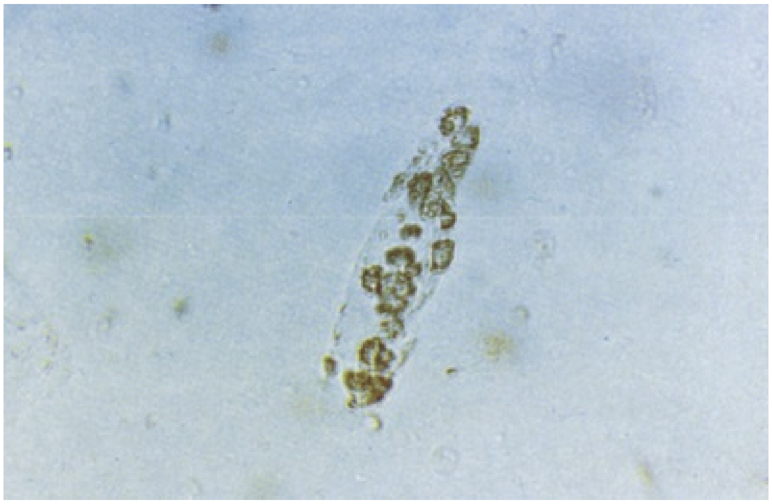

FIG. 2.15 Cellular cast. Cells entrapped in a hyaline matrix.

Crystals

Identification of crystals in the urine is particularly important in patients with stone disease because it may help determine the etiology (Fig. 2.16). Although other types of crystals may be seen in normal patients, **the identification of cystine crystals establishes the diagnosis of cystinuria.** Crystals precipitated in acidic urine include calcium oxalate, uric acid, and cystine. Crystals precipitated in an alkaline urine include calcium phosphate and triple-phosphate (struvite) crystals. Cholesterol crystals are rarely seen in the urine and are not related to urinary pH. They occur in lipiduria and remain in droplet form.

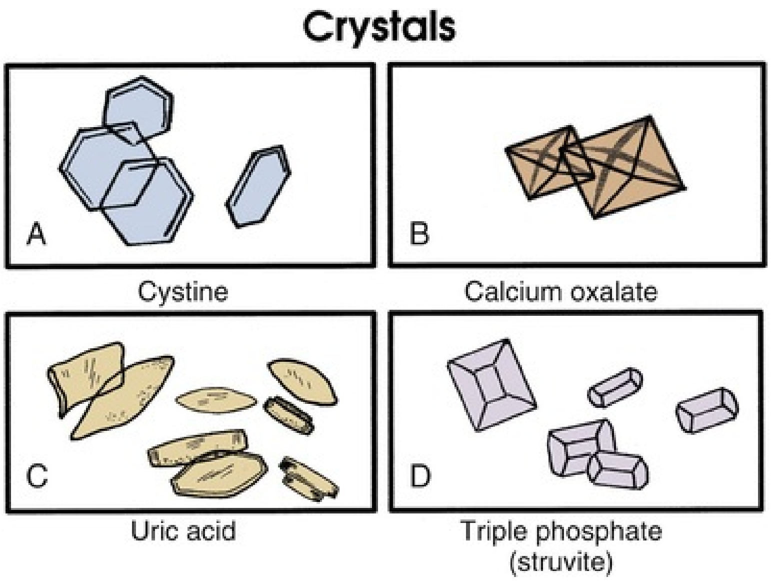

FIG. 2.16 Urinary crystals. (A) Cystine. (B) Calcium oxalate. (C) Uric acid. (D) Triple phosphate (struvite).

Bacteria

Normal urine should not contain bacteria; in a fresh uncontaminated specimen, the finding of bacteria is indicative of a UTI. Because each HPF views between 1/20,000 and 1/50,000 mL, each bacterium seen per HPF signifies a bacterial count of more than 30,000/mL. Therefore, **5 bacteria per HPF reflects colony counts of about 100,000/mL.** This is the standard concentration used to establish the diagnosis of a UTI in a clean-catch specimen. This level should apply only to women, however, in whom a clean-catch specimen is frequently contaminated. The finding of any bacteria in a properly collected midstream specimen from a male patient should be further evaluated with a urine culture.

Under high power, it is possible to distinguish various bacteria. Gram-negative rods have a characteristic bacillary shape (Fig. 2.17), whereas streptococci can be identified by their characteristic beaded chains (Figs. 2.18 and 2.19) and staphylococci can be identified when the organisms are found in clumps (Fig. 2.20).

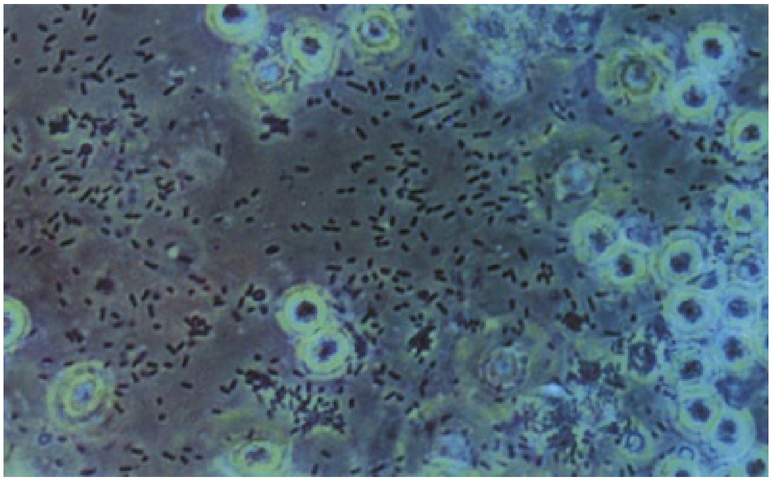

FIG. 2.17 Gram-negative bacilli. Phase microscopy of *Escherichia coli.*

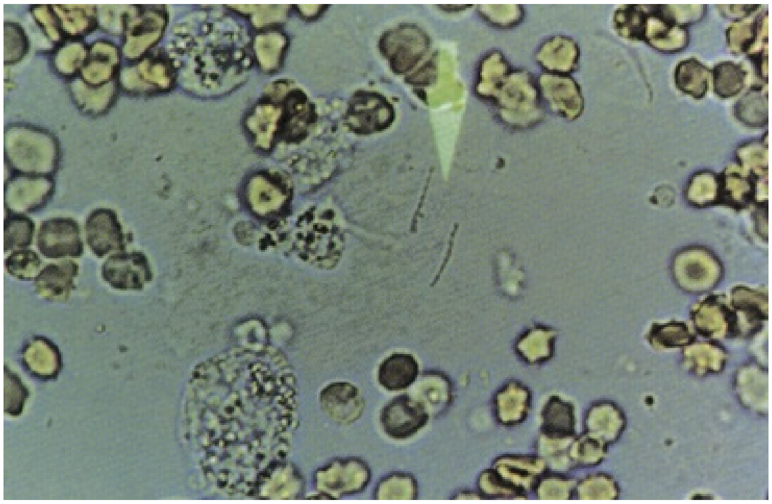

FIG. 2.18 Streptococcal urinary tract infection with typical chain formation *(arrow).*

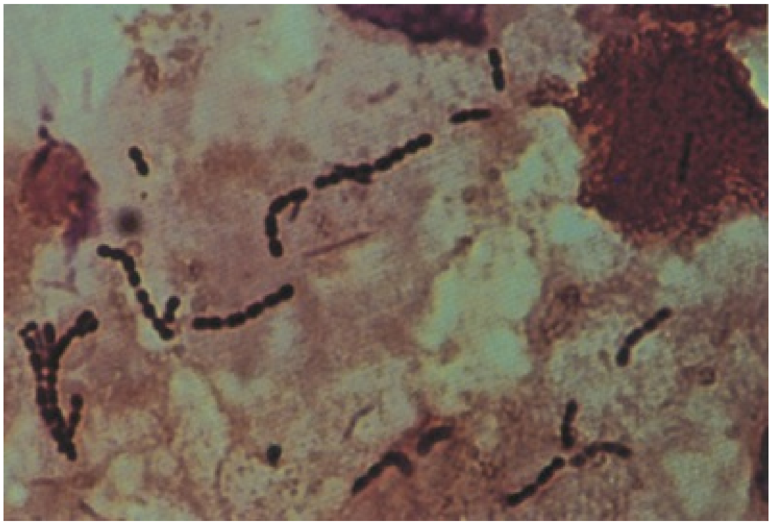

FIG. 2.19 Streptococcal urinary tract infection (Gram stain).

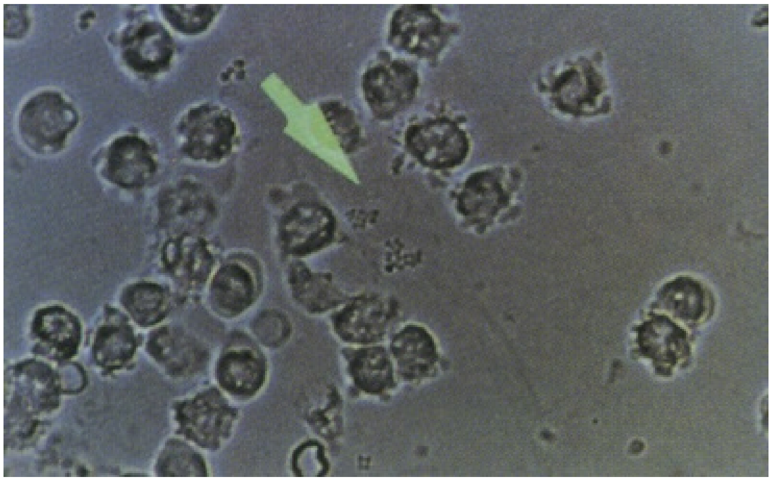

FIG. 2.20 *Staphylococcus aureus* in typical clumps *(arrow).*

Yeast

The most common yeast cells found in urine are *Candida albicans*. The biconcave oval shape of yeast can be confused with erythrocytes and calcium oxalate crystals, but **yeasts can be distinguished by their characteristic budding and hyphae** (see Fig. 2.9). Yeasts are most commonly seen in the urine of patients with diabetes mellitus or as contaminants in women with vaginal candidiasis.

Parasites

***Trichomonas vaginalis* is a frequent cause of vaginitis in women and occasionally of urethritis in men.** Trichomonads can be readily identified in a clean-catch specimen under low power (Fig. 2.21). Trichomonads are large cells with rapidly moving flagella that quickly propel the organism across the microscopic field.

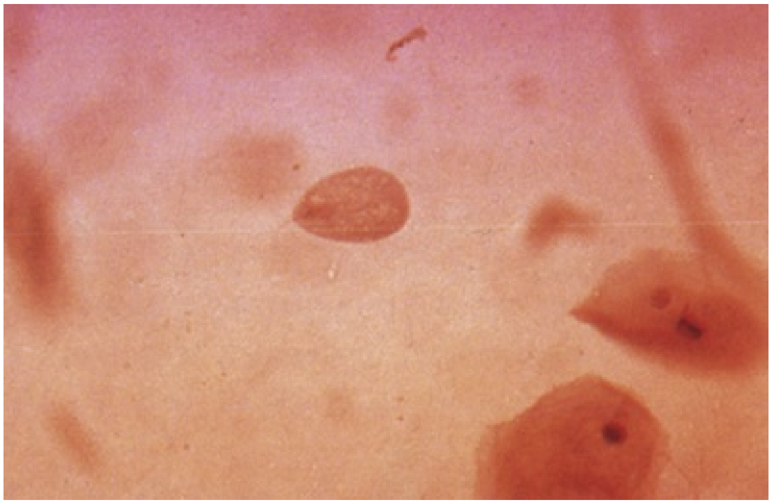

FIG. 2.21 Trichomonad with ovoid shape and motile flagella.

***Schistosoma hematobium* is a urinary tract pathogen that is not found in the United States but is extremely common in countries of the Middle East and North Africa. Examination of the urine shows the characteristic parasitic ova with a terminal spike.**

Expressed Prostatic Secretions

Although not strictly a component of the urinary sediment, the expressed prostatic secretions should be examined in any male patient suspected of having prostatitis. Normal prostatic fluid should contain few, if any, leukocytes, and the presence of a larger number or clumps of leukocytes is indicative of prostatitis. **Oval fat macrophages are found in postinfection prostatic fluid** (Figs. 2.22 and 2.23). Normal prostatic fluid contains numerous secretory granules that resemble but can be distinguished from leukocytes under high power because they do not have nuclei.

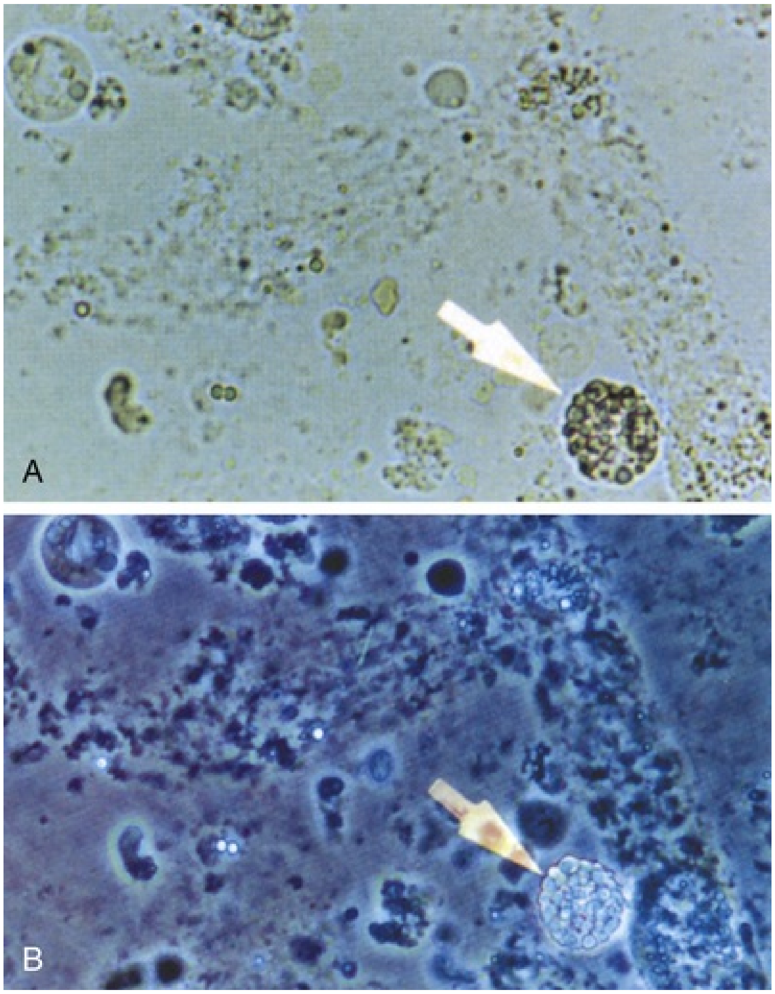

FIG. 2.22 Oval fat macrophage. (A) High-power view showing doubly refractile fat particles *(arrow).* (B) Phase microscopy of the same specimen *(arrow).*

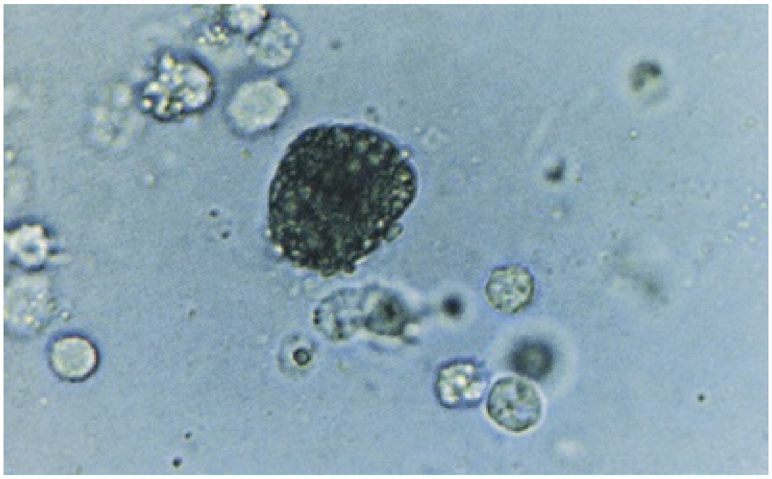

FIG. 2.23 Oval fat macrophage, high-power view. Note the fine secretory granules in the prostatic fluid.

Key Points

- A catheterized urine specimen should be obtained in the female patient with a history of recurrent UTIs or suspected contaminated specimen.
- Hematuria should be stratified into glomerular, nonglomerular, medical, and surgical causes.
- A dipstick alone is inadequate for the diagnosis of microscopic hematuria.
- AMH is defined as greater than or equal to 3 erythrocytes per HPF on a properly collected urinary specimen in the absence of an obvious benign cause.
- A urine dipstick that is positive for only leukocyte esterase or nitrites but not both should be confirmed with microscopic analysis and urine culture.

Serum Laboratory Studies

In some cases, assessing for metabolic function is incorporated in the evaluation of the urologic patient. A serum creatinine and calculated glomerular filtration rate (GFR) is often used to assess baseline or current renal function. Identifying any compromise of renal function may be useful when investigating lower or upper tract obstruction or any contributing medical renal disease. **Urgency of intervention and treatment of obstruction will be influenced by renal function.** Furthermore, the presence or history of renal disease is also used in the evaluation of conditions such as hematuria, proteinuria, and anatomic pathology as described earlier. In some cases, additional laboratory values such as serum potassium, CO_2, and liver transaminases are part of the diagnostic evaluation of malignancy or metabolic derangement seen with conditions affecting multiple organ systems including the urinary tract. A complete blood count (CBC) includes a white blood cell count, hemoglobin, hematocrit, and platelet count and may be ordered with or without a differential. This test may be ordered for perioperative purposes, during routine follow-up of patients with malignancy, and in the workup for an infectious process. A CBC may provide useful information to the urologist during evaluation of the urologic patient and help guide additional testing and workup when findings on history and physical examination suggest significant pathology within the urinary tract.

Prostate-Specific Antigen

One of the most important and controversial tumor markers identified is prostate-specific antigen (PSA). It is used by the urologist in the diagnostic evaluation of prostate pathology including cancer, benign prostatic hyperplasia (BPH), and inflammatory conditions of the prostate (prostatitis). **PSA, also known as *human kallikrein peptidase 3(hK3)*, is a serine protease and a member of the kallikrein gene family. It is produced by prostatic luminal epithelial cells.** Although there is significant disagreement across disciplines regarding its use for the detection of prostate cancer, it is a particularly useful tool for the assessment of BPH and prostatitis because of its sensitivity for the detection of prostatic pathology. The PSA level often directly correlates to prostate volume and any significant inflammatory process within the prostate gland. It is also one of the most reliable laboratory tests used when following patients with prostate cancer, particularly following treatment including radiation, radical prostatectomy, and hormonal therapy. **This test may be ordered when evaluating the male patient for prostatic diseases including prostate cancer, urinary obstruction, and symptoms caused by BPH and prostatitis**. Indications, algorithms, and implications for ordering PSA for specific pathology are covered in depth later in this text.

Urinary Markers

Urinary cytology is ordered when urothelial malignancy is suspected. Although in the past it was considered a standard part of the screening for urothelial cell carcinoma (UCC), deciding to order it in the initial evaluation is tailored to other aspects of the patient's history. Routine use as a screening tool or in the initial evaluation of AMH is not recommended and is more often used to follow patients with a known history of UCC (Davis et al., 2012, reviewed and validated 2016). However, it may be useful in patients with suspicious radiologic abnormalities or in cases in which a high-grade malignancy is suspected. **Urine cytology is highly specific for high-grade UCC, but sensitivity decreases for low-grade UCC ranging from 15.8% to 54.5%** (Steiner et al., 2008). Additional urinary markers including NMP22, BTA stat, and UroVysion FISH are available but are not recommended for routine use or for routine screening for bladder cancer (Davis et al., 2012, reviewed and validated 2016). In select cases and patients, the urologist may order one or more these tests but generally not during the initial evaluation of the urologic patient.

Additional Serum Studies

Some additional serum testing that may be ordered during the initial evaluation of the urologic patient includes serum markers for other urologic malignancies and endocrinologic studies. Examples include the standard markers for testicular cancers: alpha-fetoprotein (AFP), human chorionic gonadotropin (HCG), and lactate dehydrogenase (LDH). These are ordered during the initial evaluation of the scrotal mass or tumor that has been diagnosed on imaging such as testicular ultrasonography. Endocrinologic studies including total testosterone, free testosterone, luteinizing hormone (LH), follicle-stimulating hormone (FSH), prolactin (PRL), and thyroxine T4 may be ordered in the workup of the male patient with suspected hypogonadism. Additional serum endocrinologic studies may be ordered in the patient suspected of having endocrine disorders such as Cushing's syndrome or parathyroid disorders, and during the workup of adrenal pathology.

Key Points

- Serum creatinine and glomerular filtration rate should be ordered when renal obstruction of nephrologic disease is suspected.
- Prostate-specific antigen is a very sensitive test for prostate conditions such as BPH and prostatitis and correlates most often with prostate volume.
- Urine cytology is not recommended during the initial evaluation and screening for AMH.
- Urine cytology is very specific for high-grade urothelial carcinoma.

Office Diagnostic Procedures

Uroflowmetry and Ultrasound for Postvoid Residual

Two very common noninvasive tests performed in the urologist's office are uroflowmetry and assessment of postvoid residual (PVR). These are useful tests to obtain some basic information of the voiding status of the patient. Uroflowmetry is performed in the office with the patient voiding either in a standing or seated position. A multiple array of uroflowmeters are available on the market. In general, a peak or maximum flow rate (Qmax), mean flow rate, voided volume is obtained along with a voiding curve/pattern. This information is used to assess the patient for bladder outlet obstruction (BOO) and provide some insight as to the degree of obstruction in the male patient with suspected BPH. **If the Qmax is greater than 20 mL/s, there is a low probability of BOO. Rates between 15 mL/s and 20 mL/s indicate a low probability of BOO, but patients with significant symptomatic complaints may warrant further workup. Rates between 10 mL/s and 15 mL/s are equivocal, and rates less than 10 mL/s are often the result of BOO, urethral stricture, or detrusor impairment (Kelly, 2004).** It is recommended to interpret abnormally low flow rates with caution if the voided volume is less than 100 mL.

A PVR can be obtained as well to assess residual urine in the bladder and can complement the findings of the flow study to provide basic information about voiding. Modern office PVR is determined with a handheld bladder scanner, but if not available, a sterile catheter can be inserted. Using a sterile catheter has the disadvantage of being somewhat invasive and can cause discomfort, trauma, or infection. Threshold values of PVR are not well defined, but volumes less than 100 mL are generally considered within the acceptable range, especially in the older male patient. Conditions that can result in high PVRs include BOO, BPH, detrusor hypocontractility, neurogenic bladder, bladder diverticula, and urethral stricture disease. Further studies and testing based on results of uroflowmetry and PVR should be ordered based on the complete examination of the patient.

Cystometrography and Multichannel Urodynamic Studies

Urodynamic testing is the study of the transport, storage, and evacuation of urine. Testing is performed when a patient is in need of a more comprehensive workup of storage and voiding dysfunction that is not sufficiently diagnosed with history and physical examination. These studies are performed in the office setting, and ambulatory urodynamic studies can be obtained in select cases. **Components of more complex urodynamic studies include cystometrography, electromyography, urethral pressure profile, and**

pressure flow studies. Voiding and storage disorders and its workup are covered thoroughly later in this text.

Cystourethoscopy

Office cystourethroscopy is ordered when direct visualization and evaluation of the lower urinary tract is required. It can be performed in the office with modern flexible cystoscopic equipment. Rigid cystoscopy may be performed at the discretion of the urologist in female patients, but most often flexible cystoscopy is better tolerated. Direct examination of the urethra, bladder, and prostatic urethra in male patients can be performed for diagnostic and screening purposes, and in some cases treatments can be administered. The most common reasons office cystourethroscopy is performed is for diagnosis of lower urinary tract malignancy, urinary obstruction, or in some cases to assist with insertion of a urethral catheter. For patients with a urinary diversion such as an ileal conduit, office looposcopy can be performed to assess for pathology within the ilial conduit. This is performed with a flexible cystoscope and is generally well tolerated with only a mild amount of patient discomfort if there is significant pressure and reflux into the upper tracts. **It should be noted that use of antimicrobial prophylaxis during simple diagnostic cystourethroscopy without manipulation is not recommended as per the AUA best practice statement on urologic surgery antimicrobial prophylaxis and should only be used in patients with the risk factors listed in Table 2.3** (Wolf et al, 2008).

TABLE 2.3

Risk Factors Associated With Increased Risk for Infection Following Urologic Procedure

Advanced age
Anatomic anomalies of the urinary tract
Poor nutritional status
Smoking
Chronic corticosteroid use
Immunodeficiency
Externalized catheters
Colonized endogenous/exogenous material

Distant coexistent infection

Prolonged hospitalization

Key Points

- Uroflowmetry and assessment of PVR should be ordered when lower urinary tract obstruction is suspected.
- Urodynamic studies provide information on disorders of storage and voiding.
- Routine use of antimicrobial prophylaxis is not recommended for office cystourethroscopy, urodynamics, or cystography in the patient without risk factors.

Radiologic Imaging

During the evaluation of the urologic patient, information obtained with the history and findings on physical examination may prompt the need for radiologic testing. Although the details on the principles of imaging studies are covered in depth in later chapters, basic imaging that may be ordered for specific findings are briefly reviewed in the following section. Some imaging studies may be obtained in urology offices equipped to perform the studies, but more complex imaging such as computed tomography (CT), magnetic resonance imaging (MRI), and nuclear imaging is most often obtained at a formal radiologic facility.

Ultrasonography

Most urologists should be familiar with the indications for ordering ultrasonography of the kidneys, bladder, and prostate. In fact, more and more urologists are performing basic renal ultrasonography in the office setting. **Renal ultrasonography is ordered to obtain information on the size and shape of the kidneys, the presence or absence of hydronephrosis, anatomic abnormalities such as cysts and masses, echogenicity, and vasculature**. Medical renal disease should be suspected if there is increased cortical echogenicity relative to the liver or spleen (O'Neill, 2014). Patients with a history of stones or symptoms of flank pain may benefit from renal ultrasonography to assess for possible obstruction. However, the need for more detailed information from other studies such as CT should be weighed against the ease and convenience of performing an office ultrasonography of the kidneys. **Renal ultrasonography is not sufficient as a stand-alone imaging study for the workup of hematuria, and other cross-sectional abdominal imaging should be considered for this diagnosis.** Urologists rarely order ultrasonography of the bladder as a diagnostic study, but the bladder is often assessed during abdominal and renal ultrasonography. Large masses, large stones, and volume can be assessed by basic ultrasonography of the bladder, but limited information is provided by formal ultrasonography of the bladder. It should be noted that ultrasonography of the ureters is very difficult and should not be used as a method to diagnose conditions of the ureter such as stones or malignancy, although routine ultrasonography may be used to detect severe hydroureter.

Ultrasonography of the prostate is ordered and obtained most often in conjunction with prostate biopsy. More recently, prostate ultrasonography is being used along with MRI for the detection and diagnosis of prostate cancer (Moore and Taneja, 2016). Technology to fuse images from the MRI can be used in real-time during ultrasound-guided biopsy to target lesions within the prostate, or cognitive fusion may be used. More detailed analysis on the technology and indications for its use in the diagnosis of prostate cancer will be covered later in this text. A urologist may also order ultrasonography of the prostate without biopsy when assessing volume during the workup of BPH and/or obstruction. Information on the seminal vesicles and ejaculatory duct patency may be acquired for the assessment of ejaculatory and fertility disorders. The presence of full seminal vesicles along with a dilated ejaculatory duct may help the urologist to decide of additional testing or treatment is indicated.

Computed Tomography and Magnetic Resonance Imaging

Cross-sectional abdominal and pelvic imaging may be obtained either with CT or MRI. Both studies can be obtained with or without contrast. The principles on these more complex imaging studies will be covered later in this text, but the basic indications for ordering them in patients are when conditions of the upper tracts and bladder are suspected. The workup of microscopic and gross hematuria includes CT with contrast or MRI if there is a significant contraindication to iodinated contrast. Noncontrast CT is the most sensitive test and the gold standard for the detection of urinary stones. A history of nephrolithiasis with the onset of flank pain should prompt the ordering of a noncontrast CT of the abdomen and pelvis to assess for the presence of urinary stones. **MRI is not useful in the diagnosis and follow-up of urinary stones.** MRI is more useful in the diagnosis and evaluation of soft tissue abnormalities such as renal malignancies, tumor thrombus within the vasculature, pathology of the adrenal glands, cystic structures within the kidneys and urinary tract, and other soft tissue disorders of the abdomen, pelvis, and retroperitoneum.

Intravenous Pyelogram and Plain Radiographs

Intravenous pyelogram (IVP) and standard plain radiographs such as nephrograms have been largely eclipsed by CT and MRI. Nevertheless, there are select indications for these radiographic studies. Although IVP has been replaced by CT for the workup of urinary stones and upper tract abnormalities, especially with low-dose CT protocols that result in lower radiation exposure, one may order an IVP when dynamic imaging of upper tract excretion and obstruction is required and CT with contrast is not available. The urologist should not underestimate the usefulness of a plain radiography of the kidneys, ureters, and bladder (KUB). **A KUB may be ordered in the initial evaluation and follow-up of the nonemergent patient with a urinary stone in the ureter and/or kidneys**. As more than 70% of urinary stones are generally radio-opaque, a KUB can be useful when conservative management of urolithiasis is being pursued. For example, if a patient presents with a ureteral stone that is nonemergent and subsequent imaging may be needed for follow-up, an initial KUB may be obtained, and if the stone is visible then follow-up imaging may consist of a simple KUB rather than CT. Furthermore, patients with nonobstructing kidney stones may be successfully followed with KUB imaging if surveillance is the primary management strategy. Ultimately, patient symptoms may be used to decide if more complex imaging is warranted.

Key Points

- Renal ultrasonography can provide basic screening information on the presence of hydronephrosis and medical renal disease but is not an adequate stand-alone study for the workup of hematuria.
- CT without contrast of the abdomen and pelvis is the gold standard for detecting urinary stones.

- A KUB is a useful and easy test for the follow-up of existing nonemergent radio-opaque urinary stones.

Summary

This chapter provides an overview of the standard testing and imaging that may be part of the initial evaluation of the urologic patient. There are numerous diagnostic modalities within the urologic armamentarium, and a fundamental understanding of when to order these tests is critical when evaluating the urologic patient. The history and physical examination along with a properly collected urinalysis will help develop a differential diagnosis and direct which additional laboratory testing, office procedures, and imaging should be ordered.

Urinary Tract Imaging

Basic Principles of CT, MRI, and Plain Film Imaging

Jay T. Bishoff MD, Ardeshir R. Rastinehad DO, FACOS

With advances in all of the imaging modalities, imaging continues to play an indispensable role in the diagnosis and management of urologic diseases. Because many urologic conditions cannot be assessed by physical examination, conventional radiography has long been critical to the diagnosis of conditions of the adrenals, kidneys, ureters, and bladder. The development of new computed tomography (CT) imaging techniques, three-dimensional (3D) reconstruction, improved ultrasound modalities, advances in magnetic resonance imaging (MRI), new radiotracers for positron emission tomography (PET), and the use of intravenous contrast agents provide detailed anatomic, functional, and physiologic information about urologic conditions and are required for accurate and appropriate urologic care. With so many different imaging options available, it is important for the urologist to be familiar with different options and their correct implementation. In this chapter we discuss the indications for imaging in urology, with an emphasis on the underlying physical principles of the imaging modalities. The strengths and limitations of each modality and the techniques necessary to maximize image quality and minimize the risks and harms to urologic patients are discussed.

Conventional Radiography

Conventional radiography has largely been replaced by CT and MRI for many evaluations but remains useful for preoperative diagnosis and postoperative evaluation in a variety of different urologic conditions. Conventional radiography includes abdominal plain radiography, intravenous excretory urography, retrograde pyelography, loopography, retrograde urethrography, and cystography. Urologists frequently perform and interpret conventional radiography examinations, including fluoroscopic examinations, in the office and operating room environments.

Physics

Urologists should be familiar with the physics of conventional radiography and fluoroscopy, as well as the implications and dangers of radiation exposure to the patient and the operator. The underlying physical principles of conventional radiography involve emitting a stream of photons from an x-ray source. These photons travel through the air and strike tissue, imparting energy to that tissue. Some of the photons emerge from the patient with varying amounts of energy attenuation and strike an image recorder such as a film cassette or the input phosphor of an image-intensifier tube, thus producing an image (Fig. 3.1).

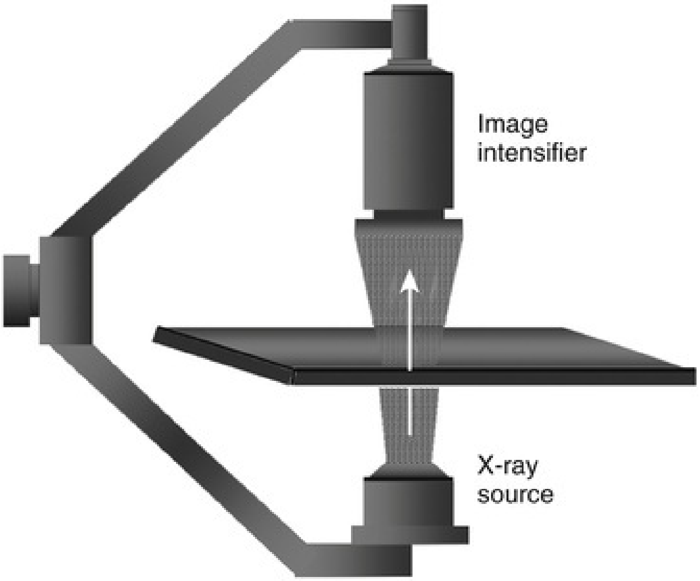

FIG. 3.1 **Recommended equipment setup for fluoroscopy.** The x-ray source located beneath the table reduces the radiation exposure to the urologist. Locating the image intensifier as close to the patient as feasible reduces scatter radiation. Equipment setup will vary based on application.

Radiation Management in Uroradiology

When diagnostic radiation passes through tissue, it creates ion pairs. The resultant charge per unit mass of air is referred to as the **radiation exposure**. The current unit of radiation exposure is measured in coulombs (C)/kg. **Absorbed dose** is the energy absorbed from the radiation exposure and is measured in units called gray (Gy). The older unit of absorbed dose was called the rad (1 rad = 100 Gy).

Because different types of radiation have different types of interaction with tissue, a conversion factor is applied to better express the amount of energy absorbed by a given tissue. The application of this conversion factor to the **absorbed dose** yields the **equivalent dose** measured in sieverts (Sv). For diagnostic x-rays the conversion factor is 1, so the absorbed dose is the same as the equivalent dose. When the amount of radiation energy absorbed by patients during therapeutic radiation is discussed, the dose is given in gray. When exposure to patients or medical personnel resulting from diagnostic ionizing radiation procedures is discussed, the dose is given in sieverts.

The distribution of energy absorption in the human body is different based on the body part being imaged and a variety of other factors. The most important risk of radiation exposure from diagnostic imaging is the development of cancer. The **effective dose** is a quantity used to denote the radiation risk (expressed in **sieverts**) to a population of patients from an imaging study. See Table 3.1 for a description of the relationship between these measures of radiation exposure.

TABLE 3.1

Units of Radiation Exposure and the Clinical Relevance of the Measures

---

RADIATION QUANTITY	TRADITIONAL UNIT	SI UNIT	CONVERSION	CLINICAL RELEVANCE
Exposure	roentgen (R)	coulomb (C)/kg	1 C/kg = 3876 R	Charge per unit mass
Absorbed dose	rad	gray (Gy)	1 Gy = 100 rad	Energy absorbed by tissue
Equivalent dose	rem	sievert (Sv)	1 Sv = 100 rem	Absorbed energy based on tissue type
Effective dose	rem	sievert		Biologic risk

		(Sv)		associated with absorbed energy

Modified from Geise RA, Morin RL: Radiation management in uroradiology. In Pollack HM, McClennan BL, ed: *Clinical urography,* ed 2, Philadelphia, 2000, Saunders, p 13.

The average person living in the United States is exposed to 6.2 mSv of radiation per year from ambient sources, such as radon and cosmic rays, and medical procedures, which account for 36% of the annual radiation exposure (National Council on Radiation Protection and Measurements [NCRP], 2012). The recommended occupational exposure limit to medical personnel is 50 mSv per year (NCRP, 2012). Exposure to the eyes and gonads has a more significant biologic impact than exposure to the extremities, so recommended exposure limits vary according to the body part. The linear no-threshold model (LNT) used in radiation protection to quantify exposition and to set regulatory limits assumes that the long-term biologic damage caused by ionizing radiation is directly proportional to the dose. **Based upon the LNT there is no safe dose of radiation.** An effective radiation dose of as little as 10 mSv may result in the development of a malignancy in 1 of 1000 individuals exposed (National Research Council of the National Academies, 2006).

Relative Radiation Levels

The assessment of biologic risk from radiation exposure is complex. Estimating the range of effective doses for various imaging modalities allows assignment of a **relative radiation level (RRL)** (Table 3.2). The effective dose from a three-phase CT of the abdomen and pelvis without and with contrast may be as high as 25 to 40 mSv. Another often-overlooked source of significant radiation exposure is seen in the use of fluoroscopy. Fluoroscopy for 1 minute results in a radiation dose to the skin equivalent to 10 times that of a single radiograph of the same anatomic area (Geise and Morin, 2000).

TABLE 3.2

Radiation Exposure From Common Urologic Imaging Procedures

RELATIVE RADIATION LEVEL (RRL)	EFFECTIVE DOSE ESTIMATED RANGE	EXAMPLE EXAMINATIONS
None	0	Ultrasound, MRI

Minimal	<0.1 mSv	Chest radiographs
Low	0.1–1.0 mSv	Lumbar spine radiographs, pelvic radiographs
Medium	1–10 mSv	Abdomen CT without contrast, nuclear medicine, bone scan, ^{99m}Tc-DMSA renal scan, IVP, retrograde pyelograms, KUB, chest CT with contrast
High	10–100 mSv	Abdomen CT without and with contrast, whole-body PET

Modified from American College of Radiology: *ACR Appropriateness Criteria Radiation Dose Assessment Introduction*. http://www.acr.org/SecondaryMainMenuCategories/quality_safety/app_criteria/RRLInformation.asp 2008.

Radiation Protection

The cumulative dose of radiation to patients increases relatively rapidly with repeated CT imaging studies or procedures guided by fluoroscopy. Certain patient populations such as those with recurrent renal calculus disease or those with a urologic malignancy may be at increased risk of developing cancer because of repeated exposures to ionizing radiation. Attempts should be made to limit axial imaging studies to the anatomic area of interest and to substitute imaging studies not requiring ionizing radiation when feasible. The cumulative dose of radiation to medical personnel (including physicians) may increase relatively rapidly in circumstances in which fluoroscopy is used.

Reduction in radiation exposure to medical personnel is achieved by three major mechanisms: (1) limiting the time of exposure; (2) maximizing distance from the radiation source; and (3) shielding. Radiation dose during fluoroscopy is directly proportional to the **time of exposure** and to the **number of exposures**. The exposure time during fluoroscopy should be minimized by using short bursts of fluoroscopy and using the “last image hold” feature of the fluoroscopy unit. Radiation beams diverge with distance, and therefore radiation exposure diminishes as the square of the distance from the radiation source. Maintaining the maximum practical distance from an active radiation source significantly decreases exposure to medical personnel. Positioning the image intensifier as close to the patient as feasible substantially reduces scatter radiation. Standard aprons, thyroid shields, radiation-resistant eye protection, and leaded gloves provide significant shielding for medical personnel and should be worn by all personnel involved in the use of fluoroscopy. **A practice of**

routinely collimating to the minimum required visual fluoroscopy field results in significant reductions in radiation exposure when compared with a usual approach to collimation. This may have important implications for decreasing the risk of malignancy in patients and operators.

Key Points: Conventional Radiography/Radiation Management in Uroradiology

- The effective radiation dose describes the potential for adverse health effects from ionizing radiation.
- The effective dose is a quantity used to denote the radiation risk (expressed in sieverts) to a population of patients from an imaging study. See Table 3.1 for a description of the relationship between these measures of radiation exposure.
- Based upon the LNT model, there is no safe dose of radiation.
- RRLs categorize diagnostic imaging studies by their estimated effective dose of radiation.
- Radiation protection for medical personnel includes (1) limiting time of exposure, (2) maximizing distance from radiation source, and (3) shielding.
- Collimating to the minimum required visual fluoroscopy field reduces exposure to the patient and operator.

Contrast Media

The urologist ordering a radiographic evaluation on a patient must consider the risks and benefits associated with a contrast-enhanced imaging study as well as alternative imaging modality that could provide the same information without the need for contrast exposure.

Many different types of contrast media have been used to enhance medical imaging and thus improve diagnostic and therapeutic decisions made by urologists. These agents are used daily throughout the world with great safety and efficacy. However, like all other pharmaceuticals, there are inherent risks associated with the use of contrast media. Adverse side effects and adverse reactions (ARs) can be a direct result from the use of contrast media and vary from minor disturbances to severe, life-threatening situations. Imaging centers must be prepared with trained personnel, readily available medications, equipment, and an ongoing system to educate clinic personnel on the recognition and treatment of ARs associated with contrast media.

Adverse Reactions to Intravascular Contrast Media

The urologists ordering a radiographic study of a patient first must consider the risks and benefits associated with a contrast-enhanced imaging study as well as alternative imaging modalities that could provide the same information without the need for radiation or contrast exposure.

ARs associated with current intravenous contrast media are uncommon: iodinated: 0.6% aggregate and 0.04% severe (Wang et al., 2008); gadolinium (Gd) based: 0.01% to 0.22% aggregate and 0.008% severe.

Low-osmolality contrast media (LOCM) are associated with low incidence of ARs, and most are not life threatening. Reports of the overall acute AR rates for allergic-like and physiologic reactions (PRs) for nonionic LOCM is 0.2% to 0.7% (Cochran et al., 2001; Mortele et al., 2005; Wang et al., 2008). Serious acute reactions have an incidence of 0.04% (4/10,000) (Katayama et al., 1990). The mortality associated with LOCM injections was reported by the USFDA and drug manufacturers' data from 1990 to 1994 to be 2.1 fatalities per 1 million contrast-enhanced studies using LOCM (Lasser et al., 1987).

The American College of Radiology has divided AR contrast agents into two categories: allergic-like reactions (ALRs) or PRs, and each is subdivided into three categories: mild, moderate, or severe (Table 3.3) (ACR Manual on Contrast Media, 2017).

TABLE 3.3

Types of Acute Reactions to Contrast Medium

MILD REACTIONS	
Self-limiting signs or symptoms	
Allergic-Like	**Physiologic**
Limited urticaria/pruritus	Limited nausea/emesis
Limited edema	Transient flushing/warm/chills
Limited throat irritation	Headache/dizziness/anxiety/altered taste
Nasal congestion	Mild hypertension
Sneezing, eye irritation, rhinorrhea	Vasovagal but resolves spontaneously
MODERATE REACTIONS	
Commonly require medical management and may become severe if not treated	
Allergic-Like	**Physiologic**
Diffuse urticaria/pruritus	Protracted nausea/emesis
Diffuse erythema	Hypertension
Facial edema	Chest pain
Throat tightness	Vasovagal responds to treatment
Wheezing/bronchospasm mild	
SEVERE REACTIONS	
Life-threatening, may result in morbidity or mortality if not treated. Cardiac arrest may occur from allergic-like as well as physiologic adverse reactions	
Allergic-Like	**Physiologic**
Diffuse edema/facial edema/shortness of breath	Vasovagal reaction resists treatment
Diffuse erythema and hypotension	Arrhythmia
Laryngeal edema with hypoxia	Seizures
Wheezing/bronchospasm with hypoxia	Hypertensive emergency
Anaphylactic shock/hypotension/tachycardia	

Data from *ACR Manual on Contrast Media,* Version 10.3, 2017.

Allergic-Like Reactions

ALRs manifest in a similar manner to allergic reactions and are now termed “allergic-like” because they are usually idiosyncratic and usually differ immunologically from true ARs. Given that an antigen-antibody response is rarely identified, allergic-like contrast medium reactions are classified as “anaphylactoid,” “allergic-like,” or “idiosyncratic” (Brockow, 2005; Bush and Swanson, 1991; Cohan and Dunnick, 1987; Dunnick and Cohan, 1994).

The exact mechanism of ALRs is not known but is thought to be a combination of systemic effects (Lasser et al., 1987, 2000)**. ALRs have not been shown to result from a true IgE antibody immunologic reaction to the contrast media** (Dawson et al.,1999). At least four mechanisms may play a role in ALRs: (1) release of vasoactive substances including histamine; (2) activation of physiologic cascades, including complement, kinin, coagulation, and fibrinolytic systems; (3) inhibition of enzymes including cholinesterase, which may cause prolonged vagal stimulation; and (4) the patient's own anxiety and fear of the actual procedure. **ALRs are not dose dependent. Severe reactions have been reported after only 1 cc was injected at the beginning of the procedure and have also occurred after completion of a full dose despite no reaction to the initial test dose** (ACR, 2017; Nelson et al., 1988; Thomsen et al., 1999).

The PRs are not allergic like and represent a physiologic response to the contrast medium molecular properties creating chemotoxicity, effects resulting from hyperosmolality, or binding of specific contrast molecules to activators. Their reactions are often dose and concentration dependent (Bush and Swanson, 1991; Cohan and Dunnick, 1987; Dunnick and Cohan, 1994; Lieberman and Seigle, 1999).

Vasovagal reactions are common PRs, characterized by hypotension and bradycardia and usually self-limiting. These reactions can be related to anxiety and have been known to occur when obtaining consent for the imaging procedure, during venous cannulation, or during administration of contrast medium.

Treatment of Contrast Reactions

Severe contrast reactions are rare but may require immediate treatment. In the case of severe reactions the patient will need emergency care and attention to respiratory and cardiovascular systems. A moderately severe reaction may progress to be severe and life threatening. To reduce the chance of significant morbidity and mortality, a plan and protocol must be in place with trained staff who are trained to recognize, assess, and treat contrast reactions. The evaluation of a patient experiencing a possible reaction includes the following:

- General appearance
- Ability to speak and characterization of the voice
- Respiratory status and oxygen saturation
- Pulse rate and characterization
- Blood pressure

Treatment: Mild Allergic-Like and Physiologic Reactions.

Observation and reassurance are often all that is needed. Usually, no intervention or medication is required. If needed, an H1-receptor blocker such as diphenhydramine (Benadryl) PO/IM/IV 1 to 2 mg/kg up to 50 mg may be helpful in this patient population. Caution is advised: these reactions may progress into a more severe category. Consequently these patients should be observed for 20 to 30 minutes. If necessary, administer chlorpheniramine 4 to 10 mg orally, intravenously, or intramuscularly and diazepam 5 mg for anxiety. For bronchospasm, oxygen 6 to 10 L/min should be administered and a β-agonist inhaler used at 2 puffs (90 mcg/puff) for a total of 180 mcg; this can be repeated up to three times.

Treatment: Moderate Allergic-Like and Physiologic Reactions.

Moderate ARs occur in 0.5% to 2% of patients and require treatment but are not immediately life threatening. These reactions are usually transient and require treatment with close observation, using hydrocortisone 100 to 500 mg IM or IV, or β-agonist inhalation for bronchospasm bronchiolar dilators (metaproterenol [Alupent], terbutaline [Brethaire], or albuterol [Proventil or Ventolin]) 2 to 3 puffs; repeat as necessary. For bronchospasm, oxygen 6 to 10 L/min should be administered and a β-agonist inhaler used at 2 puffs (90 mcg/puff) for a total of 180 mcg; this can be repeated up to three times. Epinephrine can be added to moderate or severe bronchospasm (see the following for epinephrine dosing).

Treatment: Severe Allergic-Like and Physiologic Reactions.

Life-threatening reactions occur in approximately 1/1000 uses for high osmolar agents and are far less frequent for LOCM, with both types of agents resulting in mortality rates of 1/170,000 uses (Spring et al., 1997). Immediate treatment is required. The patient usually requires emergency care, involving particular attention to the respiratory and cardiovascular systems. If bronchospasm is severe and not responsive to inhalers, or if an upper airway edema (including laryngospasm) is present, epinephrine should be used promptly. **Rapid administration of epinephrine is the treatment of choice for severe contrast reactions. Epinephrine can be administered IV in the dose of 0.1 mL/kg of 1:10,000 dilution or (0.01 mg/kg) slowly into a running IV infusion of saline and can be repeated every 5 to 15 minutes as needed. The maximum single dose is 1.0 mL (0.1 mg) and can be repeated as needed to a total dose of 1 mg.**

If no IV access is available, the recommended intramuscular dose of epinephrine is 0.01 mg/kg of 1:1000 dilution (0.01 mL/kg) to a maximum of 0.15 mg of 1:1000 if less than 30 kg (0.3 mg if weight is >30 kg) is injected intramuscularly in the lateral thigh. This can be repeated every 5 to 15 minutes up to 1 mL (1 mg) total dose. Subcutaneous injection is much less effective (ACR Manual, 2017; Lightfoot et al., 2009). Epinephrine must be administered with care to patients who have cardiac disease or those who are taking beta-blockers because the unopposed alpha effects of epinephrine in these patients may cause severe hypertension or angina.

Antihistamines do not have a major role in the treatment of severe reactions. Careful monitoring of patient vital signs is paramount; the presence of both hypotension and tachycardia indicates a higher likelihood of anaphylactic reaction. Bradycardia is a sign of vasovagal reaction and therefore the use of beta-blockers is to be avoided. Hypotension resulting from an anaphylactic reaction can be treated with intravenous iso-osmolar fluids (e.g., 0.9% normal saline or Ringer's lactate solution): several liters of fluid may be needed before obtaining a significant hemodynamic response. If fluid and oxygen are unsuccessful in reversing the patient's hypotension, the use of vasopressors is indicated. The most effective vasopressor is dopamine. Dopamine should be used at infusion rates between 2 and 10 mcg/kg/min.

Premedication

There is no known premedication strategy that will eliminate the risk of a severe adverse reaction to contrast media. The regimens suggested in the literature include the use of corticosteroids, antihistamines, H_1 and H_2 antagonists, and ephedrine. Patients at high risk should be premedicated with corticosteroids and possibly with antihistamines 12 to 24 hours before and after use of intravenous radiographic contrast media (IRCM). LOCM should be used in these patients. Several premedication regimens have been proposed to reduce the frequency and/or severity of reactions to contrast media. Two frequently used regimens are outlined in Box 3.1.

Box 3.1

Premedication Strategies to Reduce Severity of Reactions to Contrast Media

1. Prednisone: 50 mg by mouth at 13 hours, 7 hours, and 1 hour before contrast media injection
   Plus diphenhydramine (Benadryl) 50 mg intravenously, intramuscularly, or by mouth 1 hour before contrast medium injection
2. Methylprednisolone (Medrol): 32 mg by mouth 12 hours and 2 hours before contrast media injection
   Plus diphenhydramine (Benadryl): 50 mg intravenously, intramuscularly, or by mouth 1 hour before contrast medium injection

Corticosteroid Premedication.

Corticosteroid administered before contrast imaging is used to lower the likelihood of an ALR in patients thought to be at risk for a reaction. It has been demonstrated that the use of nonionic contrast media combined with a premedication strategy including corticosteroids results in a reduction in reaction rates compared to other protocols for patients who have experienced a prior contrast media–induced reaction. A randomized trial of premedication for average-risk patients before high-osmolality iodinated contrast medium showed a reduction in mild, intermediate, and severe reactions (Lasser et al., 1987). However, high-osmolality agents are no longer used for intravascular purposes. Another small, randomized trial reported decreased reactions in premedicated patients receiving low-osmolality iodinated contrast medium (O'Malley et al., 2011).

Because severe reactions are rare events, it is difficult to design a study that would be adequately powered to measure a difference. It is estimated that the number of patients needed to premedicate to prevent one reaction in high-risk patients was 69 for avoidance of any reaction, and 569 patients to prevent a severe reaction (Mervak et al., 2015). It is estimated that the number needed to treat to prevent a lethal reaction in high-risk patients would be approximately 50,000 patients (Davenport et al., 2016).

There are no published studies addressing the use of premedication strategies before oral contrast or gadolinium-based intravenous contrast medium in high-risk patients. The current premedication recommendations in these patients are extrapolated from patients receiving intravascular iodinated contrast media.

The risks to patients for premedication with corticosteroids are small and include leukocytosis, asymptomatic hyperglycemia, and possible infection risk (Davenport et al., 2011; Davenport et al., 2016; Lasser, 1988). Diphenhydramine may result in drowsiness.

Premedication Strategies.

Oral administration of steroids seems preferable to intravascular administration, with prednisone and methylprednisolone being equally effective. If the patient is unable to take oral medication, 200 mg of hydrocortisone intravenously may be substituted for oral prednisone. **One consistent finding is that steroids should be given at least 6 hours before the injection of contrast media regardless of the route of steroid administration. It is clear that administration for 3 hours or less before contrast does not decrease the incidence of ARs** (Greenberger et al., 1984; Greenberger et al., 1985; Lasser, 1988; Lasser et al., 1987; O'Malley et al., 2011). The minimum duration of premedication is not known. Most studies show that 32 mg of oral methylprednisolone 2 hours before IV use of high-osmolality iodinated contrast in average-risk patients was not effective at prevention of AR, whereas two doses of 32 mg of oral methylprednisolone, one taken 12 hours before contrast and the second taken 2 hours before contrast, was effective (O'Malley et al., 2011).

Supplemental administration of an H_1 antihistamine (e.g., diphenhydramine), orally or intravenously, may reduce the frequency of urticaria, angioedema, and respiratory symptoms.

In emergency situations, intravenous corticosteroid (e.g., 200 mg hydrocortisone) every 4 hours plus an H_1 antihistamine (e.g., 50 mg diphenhydramine) 1 hour before the procedure has been used. In patients who have a prior documented contrast reaction, the use of a different contrast agent has been advocated and may be protective. Switching to a different agent should be in combination with a premedication regimen.

Although rare, ARs have been reported after extravascular instillation of contrast agents (e.g., retrograde pyelography). **In patients with a positive history of previous severe reactions to contrast agents undergoing a nonvascular study, premedication with corticosteroids should be considered.**

Premedication Regimens.

Elective premedication with 12 to 13 hours before administration of contrast medium is as follows:

Prednisone: 50 mg oral prednisone at 13 hours, 7 hours, and 1 hour before contrast medium administration, plus 50 mg diphenhydramine IV, IM, or PO 1 hour before contrast administration

or

Methylprednisolone: 32 mg orally 12 hours and again 2 hours before contrast medium administration, plus 50 mg diphenhydramine IV, IM, or PO 1 hour before contrast administration

For patients unable to take oral medication, substitute 200 mg IV hydrocortisone for each does of the or prednisone may be used (Lasser et al., 1987; Mervak et al., 2017).

Accelerated IV Premedication.

Premedication regimens less than 4 to 5 hours before administration of contrast medium, with oral or IV medications, have not been shown to be effective. The accelerated 4- to 5-hour regimen is supported by a case series and a retrospective cohort study of 828 patients (Mervak et al., 2017).

1. Methylprednisolone sodium succinate (e.g., Solu-Medrol) 40 mg IV or hydrocortisone sodium succinate (e.g., Solu-Cortef) 200 mg IV immediately and then every 4 hours until contrast medium administration, plus diphenhydramine 50 mg IV 1 hour before contrast medium administration. This regimen usually lasts 4 to 5 hours.
2. Dexamethasone sodium sulfate (e.g., Decadron) 7.5 mg IV immediately and then every 4 hours until contrast medium administration, plus diphenhydramine 50 mg IV 1 hour before contrast medium

administration. This regimen may be useful in patients with an allergy to methylprednisolone and usually lasts 4 to 5 hours.

3. Methylprednisolone sodium succinate (e.g., Solu-Medrol) 40 mg IV or hydrocortisone sodium succinate (e.g., Solu-Cortef) 200 mg IV, plus diphenhydramine 50 mg IV, each 1 hour before contrast medium administration. This regimen, and all other regimens with a duration less than 4 to 5 hours, has no evidence of efficacy. It may be considered in emergent situations when there are no alternatives (ACR, 2017).

Delayed Contrast Reactions

Delayed contrast reactions can occur from 3 hours to 7 days after the administration of contrast. These reactions are identified in as many as 14% to 30% of patients after the injection of ionic monomers and in 8% to 10% of patients after the injection of nonionic monomers. The most common of delayed reactions are allergic-like and cutaneous reactions with reported incidence of 0.5% to 9%. The most common reactions include a cutaneous xanthem or pruritis without urticaria. Nausea, vomiting, drowsiness, headache, and flulike symptoms also may occur. These signs and symptoms typically resolve spontaneously (Loh et al., 2010).

Specific Contrast Considerations

Allergy.

Patients who have had a prior ALR to contrast medium have a fivefold increased risk for developing a future ALR if exposed to the same class of contrast agent (Jung et al., 2012; Katayama et al., 1990). Patients who have allergies unrelated to contrast are at a two to three times increased risk for an ALR to contrast. Patients with shellfish or iodine allergies are at no greater risk from iodinated contrast medium than are patients with other allergies (Beaty et al., 2008; Boehm, 2008). Patients who have had a reaction to one class of contrast medium are not at higher risk or chance of having a reaction to another type of contrast medium.

Anxiety.

Contrast reactions are more common in patients with anxiety and may need reassurance but do not require premedication (Lalli, 1974).

Asthma.

A history of asthma increases the chance of an ALR and bronchospasm. Notwithstanding, premedicating based on the history of asthma alone is not recommended (Shehadi, 1975).

Beta-Blockers.

It has been suggested that the use of beta-blockers can lower the threshold for contrast reactions, reduce the response to treatment, and increase the risk of more severe contrast reactions (Lane et al., 1993). This risk is modest and consequently premedication and cessation of beta-blockers are not recommended before use of contrast medium.

Cardiac Abnormalities.

Patients with underlying severe cardiac disease, including chest pain and cardiac arrest, have an increased incidence and/or severity of cardiovascular side effects. Pulmonary angiography and intracardiac and coronary artery injections carry the highest degree of risk. Possible reactions include hypotension, tachycardia, and arrhythmias. More severe, but uncommon, reactions include congestive heart failure, pulmonary edema, and cardiac arrest. Premedication is not recommended based solely upon cardiac status.

Hyperthyroidism.

Iodinated contrast media does not affect thyroid function in patients with a normal functioning thyroid. Patients with hyperthyroidism may develop thyrotoxicosis after exposure to an iodinated contrast medium, but this is a rare event (van der Molen et al., 2004). During acute thyroid storm, iodinated contrast can potentiate thyrotoxicosis and should be avoided in these patients. Iodinated contrast medium can interfere with patients undergoing radioactive iodine therapy or radioactive iodine imaging of the thyroid, and a washout period is recommended after imaging with iodinated contrast medium of 3 to 6 weeks (ACR, 2017; Silberstein et al., 2012).

Myasthenia Gravis.

The use of intravenous iodinated contrast medium causing an exacerbation of symptoms in patients with myasthenia gravis (MG) is controversial. Myasthenic exacerbation occurs in approximately 6% of patients with MG exposed to iodinated contrast compared with 1% of patients with MG undergoing contrast

CT imaging. Premedication is not recommended solely based on the history of MG (Mehrizi and Pascuzzi, 2014; Somashekar et al., 2013).

Pheochromocytoma.

There is no evidence that the use of currently available iodinated or gadolinium contrast medium will induce a hypertensive crisis in patients with pheochromocytoma (Mukherjee et al., 1997).

Sickle Cell Trait and Disease.

It has been suggested that contrast medium in sickle cell disease or trait patients may increase the risk of sickle crisis. This has not been seen with the use of current iodinated or gadolinium contrast medium (Morcos, 2005).

Extravasation of Contrast Material.

Large volume extravasation can be seen with power injections not monitored with electrical skin impedance devices that detect extravasation and arrest the injection process. When large volume extravasation of IRCM occurs, the result can be swelling, edema, erythema, pain, and cellulitis. The most severe consequences may not be manifest immediately, and the inflammatory reaction usually reaches a maximum in 24 to 48 hours. The primary underlying mechanism is believed to be the hyperosmolality of the contrast agent. Mechanical compression resulting from a compartment syndrome may also occur, leading to tissue necrosis. Management steps are immediate cessation of injection, notification of responsible and referring physicians, and elevation of the affected extremity above the level of the heart. If large volume of extravasate occurs, it is recommended to manually massage to promote drainage. If the patient becomes symptomatic, plastic surgery consultation may also be needed. Admission to the hospital for observation or frequent follow-up in clinic may be necessary in some cases of large volume extravasation.

Postcontrast Acute Kidney Injury.

Postcontrast acute kidney injury (PC-AKI) is a nonspecific term assigned to an acute, sudden deterioration in kidney function within 48 hours after IV administration of contrast medium. Contrast-induced nephropathy (CIN) is specific for a sudden decrease in kidney function caused by IV administration of iodinated contrast medium.

The precise pathophysiology is not entirely understood, and many different factors have been implicated: vasoconstriction, direct tubular toxicity, osmotic mechanisms, and chemotoxic mechanisms (Heinrich et al., 2005; Liu et al., 2012).

When used at FDA-recommended doses, gadolinium-based contrast media either do not cause CIN or the incidence is extremely low. However, if administered at higher than FDA-approved doses, gadolinium-based contrast media (GBCM) are more nephrotoxic than isoattenuating doses of iodinated contrast media (Briguori et al., 2006).

Although there are no standard criteria for CIN, the diagnosis can be made if one of the following occurs within 48 hours after administration of iodinated contrast medium: increase in serum creatinine of >0.3 mg/dL, >50% increase in serum creatinine from baseline, or urine output reduced to <0.5 mL/kg/h for at least 6 hours (Mehta et al., 2007).

Four large studies of more than 40,000 patients have addressed CIN, and all four studies have shown that CIN is less common than previously reported. For patients with a stable baseline estimated glomerular filtration rate (eGFR) of at least 45 mL/min/1.73 m^2 IV, iodinated contrast media are not an independent risk for CIN, and in patients with a eGFR 30 to 44 mL/min/1.73 m^2, IV iodinated contrast media are either not nephrotoxic or rarely the cause of CIN (Davenport et al., 2013a; Davenport et al., 2013b; McDonald et al., 2013; McDonald et al., 2014). IV iodinated contrast material appears to be an independent risk factor for CIN in patients with stage IV and stage V chronic kidney disease whose eGFR is less than 30 mL/min/1.73 m^2.

High doses of IRCM can impair renal function in some patients for 3 to 5 days, and the creatinine level usually returns to baseline in 10 to 14 days. The incidence of contrast agent–related nephropathy is estimated to be 2% to 5%, and of those with CIN, up to 25% have persistent renal dysfunction. Clinical manifestations are highly variable and may be absent or proceed to oliguria. CIN in patients with normal kidney function is rare (Kelly et al., 2008; Pannu et al., 2006). CIN is the third most common cause of acute kidney failure in hospitalized patients (Nash et al., 2002).

Isolating specific risk factors for CIN have proven to be difficult to determine. There is general consensus that the most important preexisting risk factor for CIN is severe renal insufficiency. Other risk factors that have been suspected to lead to CIN include diabetes mellitus, dehydration, cardiovascular disease, diuretic use, advanced age, multiple myeloma, hypertension, hyperuricemia, and repeated doses of iodinated contrast in a short period of time.

The most common patient-related risk factors for CIN are chronic kidney disease (creatinine clearance <60 mL/min), diabetes mellitus, dehydration, diuretic use, advanced age, congestive heart failure, age, hypertension, low hematocrit, and ventricular ejection fraction less than 40%. The patients at highest risk for developing CIN are those with both diabetes *and* preexisting renal insufficiency. Other risk factors are concomitant exposure to chemotherapy, aminoglycoside or nonsteroidal anti-inflammatory agents, hyperuricemia, and diseases that affect renal hemodynamics, such as end-stage liver disease and nephrotic syndrome. Patients with a diagnosis of a paraproteinemia syndrome/disease (e.g., multiple myeloma) or a history of a kidney transplant, renal tumor, renal surgery, or single kidney may also be at higher risk of CIN.

The most common non–patient-related causes are high osmolar contrast agents, ionic contrast, increased contrast viscosity, and multiple contrast-enhanced studies performed within a short period and large contrast volume infused (Pannu et al., 2006).

Despite significant discussion on the part of radiologists and urologists, the literature does not support an absolute serum creatinine level that prohibits the use of contrast media. Prevention of CIN has been the subject of many research studies, and the results have been summarized by several different meta-analyses. In these meta-analyses the baseline serum creatinine of study participants ranged from 0.9 to 2.5 mg/dL. In one survey the policies regarding the cutoff value for serum creatinine varied widely among radiology practices: 35% of respondents used 1.5 mg/dL, 27% used 1.7 mg/dL, and 31% used 2.0 mg/dL (mean 1.78 mg/dL) as a cutoff value in patients with no risk factors other than elevated creatinine; threshold values were slightly lower in people with diabetes (mean 1.68 mg/dL). Patients in end-stage renal disease who have no remaining natural renal function are no longer at risk for CIN and may receive LOCM or iso-osmolar contrast medium (IOCM) (Elicker et al., 2006).

Some radiologists prefer to stratify patients by eGFR instead of serum creatinine, and several studies support this practice. One report showed no risk of CIN from IV iodinated contrast regardless of baseline eGFR (McDonald et al., 2014). Another report identified patients with an eGFR less than 30 mL/min/1.73 m^2 were at significant risk of CIN, and patients with an eGFR 30 to 44 mL/min/1.73 m^2 were at some risk for CIN but not statistically significant risk (Davenport et al., 2013). One report showed that a higher percentage of patients presenting for contrast-enhanced CT had an eGFR less than 60 mL/min/1.73 m^2 than had a serum creatinine greater than 1.4 mg/dL, favoring the use of eGFR instead of serum creatinine (Herts et al., 2008). Presently, there is minimal evidence to suggest that IV iodinated contrast material acts as an independent risk factor for CIN in patient with an eGFR of more than 30 mL/min/1.73 m^2. Therefore it seems that this threshold is supported by the greatest amount of evidence.

The American College of Radiology recommends a baseline serum creatinine level before receiving IV iodinated contrast medium if one or more of the following risk factors are present (ACR Manual on Contrast Media, 2017):

- Age >60 years
- History of renal disease:
    - Dialysis
    - Kidney transplant
    - Solitary kidney
    - Renal cancer
    - Renal surgery
    - Hypertension requiring medical management
    - History of diabetes mellitus
    - Metformin drug combinations

Prevention of CIN is of great concern and has been a subject of many different studies. Hydration is the major preventative action against CIN. Periprocedural IV hydration with 0.9% saline at 100 mL/h 12 hours before to 12 hours after has been shown to decrease the incidence of CIN after intravenous contrast use (Solomon et al., 2007). **The use of sodium bicarbonate has not been definitively shown to prevent CIN in patients receiving IV iodinated contrast material. (The use of *N*-acetylcysteine for the prevention of CIN is controversial** [Safirestein et al., 2000].**) Currently there is insufficient evidence to make a definitive recommendation for its use, and therefore it should not be considered a substitute for appropriate screening and hydration** (Newhouse and RoyChoudhury, 2013; Zoungas et al., 2009). Furosemide was found to increase the risk of developing CIN (Kelly et al., 2008; Pannu et al., 2006).

Metformin and Iodinated Contrast.

Metformin, an oral antihyperglycemic drug used to treat diabetes, is eliminated unchanged through the kidneys, most likely by glomerular filtration and tubular excretion. As a biguanide, it stimulates intestinal production of lactic acid. Some conditions can reduce metformin excretion or increase serum lactate. Such conditions include renal disease (decreases metformin excretion), liver disease (decreases lactic acid metabolism), and cardiac disease (increases anaerobic metabolism). **Patients with type 2 diabetes mellitus on metformin may have an accumulation of the drug after administering IRCM, resulting in biguanide lactic acidosis; they experience vomiting, diarrhea, and somnolence. This condition is fatal in approximately 50% of cases** (Wiholm and Myrhed, 1993). **Biguanide lactic acidosis is rare in patients with normal renal function. Consequently, in patients with normal renal function and no known comorbidities, there is no need to discontinue metformin before IRCM use, nor is there a need to check creatinine after the imaging study. However, in patients with renal insufficiency, metformin should be discontinued the day of the study and withheld for 48 hours. Postprocedure creatinine should be measured at 48 hours and metformin started once kidney function is normal** (Bailey and Turner, 1996). **It is not necessary to discontinue metformin before gadolinium-enhanced magnetic resonance (MR) studies when the amount of gadolinium administered is in the usual dose range of 0.1 to 0.3 mmol per kg of body weight.**

Metformin is an antihyperglycemic agent used to treat diabetes mellitus and other conditions that is excreted in the kidneys by glomerular filtration and tubular excretion. The most significant adverse effect of metformin therapy is the possibility of developing metformin-associated lactic acidosis, which is rare (0.084 cases per 1000 patient-years) but has a mortality of 50% in susceptible patients.

The management of patients taking metformin should include the following information. Patients taking metformin are not at higher risk for CIN than other patients. Iodinated contrast is a potential concern for furthering renal damage in patients with acute kidney injury and those with chronic (stage IV or stage V) kidney disease. There have been no reports of lactic acidosis after IV iodinated contrast medium in patients properly selected for metformin considerations.

Recommendations[a] for patients taking metformin are classified into two categories:

1. Patients with no evidence of acute kidney injury (AKI) and eGFR ≥ 30

mL/min/1.73 m^2 do not need to discontinue metformin before or after IV administration of iodinated contrast media and do not need assessment of renal function after imaging.

2. Patients with AKI or CKD (stage IV, stage V, eGFR < 30 mL/min/1.73 m^2) or are having arterial catheter studies that may result in emboli of any type to the kidneys should have their metformin temporarily discontinued before the procedure for 48 hours and then restarted only after renal function has been revaluated and found to be normal.

Metformin and Gadolinium.

It is not necessary to discontinue metformin before contrast medium administration when the amount of gadolinium contrast material is in the normal and usual dose range of 0.1 to 0.3 mmol/kg body weight.

Magnetic Resonance Imaging Contrast Agents

Because MRI offers previously unseen detailed soft tissue imaging compared with CT, it was initially believed that MRI would not require contrast enhancement. However, by 2005, almost 50% of MRI studies were being performed with contrast media. Extracellular MRI contrast agents contain paramagnetic metal ions. Copper, manganese, and gadolinium were the potential paramagnetic ions for use with MRI. Gadolinium, however, is the most powerful, having seven unpaired electrons, but its toxicity required encapsulation by a chelate. Paramagnetic agents such as gadolinium are positive enhancers, reducing the T1 and T2 relaxation times and increasing tissue signal intensity on T1-weighted images, while having little effect on T2-weighted images.

Gadolinium

Acute adverse reactions are encountered less frequently with GBCM than after administration of iodinated contrast media. The frequency of all acute adverse events after an injection of 0.1 or 0.2 mmol/kg of gadolinium chelate ranges from 0.07% to 2.4%. The vast majority of these reactions are mild, including coldness at the injection site, nausea, emesis, headache, warmth or pain at the injection site, paresthesias, dizziness, and itching. Reactions resembling an ALR occur in 0.004% to 0.7% of cases. Reactions consisting of rash, hives, or urticaria are most frequent; the patient rarely develops bronchospasm. The severe, life-threatening anaphylactoid or nonallergic anaphylactic reactions are exceedingly rare (0.0001% to 0.001%). In a meta-analysis of 687,000 gadolinium doses for MRI, there were only 5 severe reactions. In another survey based on 20 million administered doses there were 55 cases (0.0003%) of severe reactions. Fatal reactions to gadolinium chelate agents have been reported, but they are extremely rare events. There have been no documented vaso-occlusive or hemolytic complications when administering GBCM to patients with sickle cell disease (Dillman et al., 2011; Elicker et al., 2006). Gadolinium agents are considered to have no nephrotoxicity at approved doses for MRI. However, because of the risk of nephrogenic systemic fibrosis (NSF) in patients with severe renal dysfunction, its use in this patient population requires some precaution and a review of the current recommendations.

Extracellular MRI agents are known to interfere with some serum chemistry assays. For example, serum calcium tests often are measured as a false reading of hypocalcemia for 24 hours after MRI with gadolinium enhancement, even though serum calcium is actually in the normal range. Other tests, including iron, magnesium, iron-binding capacity, and zinc, may also have spurious results. Biochemical assessment is more reliable when performed 24 hours after exposure to GBCM.

Nephrogenic Systemic Fibrosis

NSF is a fibrosing disease of the skin, subcutaneous tissues, lungs, esophagus, heart, and skeletal muscles. Initial symptoms typically include skin thickening and/or pruritus. Symptoms and signs may develop and progress rapidly, with some affected patients developing contractures and joint immobility within days of exposure. Death may result in some patients, presumably as a result of visceral organ involvement.

In 1997 NSF was described in dialysis patients who had not been exposed to GBCM. The condition was previously known as nephrogenic fibrosing dermopathy. In 2006 and again in 2007 independent reports surfaced defining a strong association with GBCM in patients with advanced renal disease (Grobner, 2006; Mackerman et al., 2007). **It is now accepted that GBCM exposure is a necessary factor in the development of NSF. Onset of NSF varies between 2 days and 3 months, with rare cases appearing years after exposure** (Shabana et al., 2008). **Early manifestations include subacute swelling of distal extremities, followed by severe skin induration and later even organ involvement.** In a 2007 survey performed by the American College of Radiology, 156 cases of NSF were reported by 27 responding institutions; 140 of these 156 patients were known to have received GBCM. In 78 patients, the specific GBCM was known: 45 of them received gadodiamide, 17 gadopentetate dimeglumine, 13 gadoversetamide, and 3 gadobenate dimeglumine. NSF after gadoteridol administration has also been reported. Many of the cases in which agents other than gadodiamide and gadopentetate dimeglumine were used are confounded by the fact that affected patients were injected with other agents as well (ACR, 2017). Between 12% and 20% of confirmed cases of NSF have occurred in patients with acute kidney injury. Patients with end-stage kidney disease and eGFR less than 15 mL/min/1.73 m^2 and severe CKD and eGFR 15 to 29 mL/min/1.73 m^2 have a 1% to 7% chance of developing NSF after MRI with gadolinium agents (Todd et al., 2007).

Patients with glomerular filtration rate (GFR) less than 30 mL/min/1.73 m^2 not on chronic dialysis are the most difficult patient population in terms of choosing imaging modality. They are at risk for CIN if exposed to iodinated contrast media for CT imaging and are at significant risk of developing NSF if exposed to GBCM during MRI. Recent data suggest that the risk of NSF may be greatest in patients with a GFR of less than 15 mL/min/1.73 m^2 who have a 1% to 7% chance of developing NSF after GBCM MRI, with the incidence being much less in patients with GFRs that are higher (Kanal et al., 2008). There is a single report of NSF in a patient with eGFR greater than 30 mL/min/1.73 m^2. In the chronic kidney disease patient population, it is recommended that contrast media be avoided if possible. If MRI contrast media is absolutely essential, use of the lowest possible doses (needed to obtain a diagnostic study) of selected GBCM is recommended. In this setting, the patient should be informed of the risks of GBCM administration and must give their consent to proceed. There is no proof that any GBCM is completely safe in this patient group; however, some have suggested avoiding gadodiamide and considering use of macrocyclic agents (Kanal et al., 2008). Patients with CKD but GFR exceeding 30 mL/min/1.73 m^2 are considered to be at extremely low or no risk for developing NSF if a dose of GBCM of 0.1 mmol/kg or less is used. Patients with GFR greater than 60 mL/min/1.73 m^2 do not appear to be at increased risk of developing NSF; the current consensus is that all GBCM can be administered safely to these patients.

The exact mechanism causing NSF is not known. It is believed, but not definitely proven, that gadolinium ions dissociate from the chelates in gadolinium-based contrast agent (GBCA) patients with poor renal clearance. The free gadolinium binds with anions such as phosphate, and the result is an insoluble precipitate that becomes deposited in different tissues with subsequent fibrotic reaction (Abraham et al., 2008; Collidge et al., 2007).

The ACR Committee on Drugs and Contrast Media (ACR Manual on Contrast Media, 2017) has concluded that patients considered to be at risk for NSF and who should have precontrast renal function testing include patients with a history of the following:

- Renal disease:
    - Dialysis
    - Severe or end-stage CKD (eGFR <30 mL/min/1.73 m^2) without dialysis
    - AKI
    - Solitary kidney
    - Known kidney cancer
- Hypertension requiring medical therapy
- Diabetes mellitus

Key Points: Contrast Media

- People with type II diabetes with renal insufficiency on oral metformin biguanide hyperglycemic therapy are at risk for developing biguanide lactic acidosis after exposure to intravascular radiologic contrast media and should stop metformin the day before the procedure and restart 48 hours after if they have a normal or baseline serum creatinine.
- Patients at risk for adverse reaction to contrast include patients with previous adverse reaction, history of asthma, severe cardiac disease, renal insufficiency, dehydration, sickle cell anemia, anxiety, apprehension, hyperthyroidism, and presence of adrenal pheochromocytoma.
- Epinephrine can be administered IV in the dose of 0.01 mg/kg of 1:10,000 dilution or 0.1 mL/kg slowly into a running IV infusion of saline and can be repeated every 5 to 15 minutes as needed. If no IV access is available, the recommended intramuscular dose of epinephrine is 0.01 mg/kg of 1:1000

dilution (or 0.01 mL/kg to a maximum of 0.15 mg of 1:1000 if <30 kg; 0.3 mg if weight is >30 kg) injected intramuscularly in the lateral thigh.

- Patients at greatest risk for contrast-induced nephropathy are those with diabetes mellitus and dehydration.
- Steroids given to prevent adverse contrast agents should be given at least 6 hours before injection.

Intravenous Urography

Once the mainstay of urologic imaging, the intravenous excretory urographic (IVU) study has almost been replaced by CT and MRI imaging. With the ability of new scanners to perform axial, sagittal, and coronal reconstruction of the upper tract urinary system, practically all of the data and information obtained by traditional IVU can be realized with CT. In addition, some parenchymal defects, cysts, and tumors can be better delineated with CT than IVU.

Technique

Bowel prep may help to visualize the entire ureters and upper collecting systems. Patients with chronic constipation may benefit most from complete bowel prep with clear liquids for 12 to 24 hours and an enema 2 hours before the procedure.

Before injection of contrast, a scout radiograph or KUB (kidneys, ureters, bladder) film is taken demonstrating the top of the kidneys and the entire pelvis to the pubic symphysis. This allows determination of adequate bowel prep, confirms correct positioning, and exposes kidney stones or bladder stones.

Contrast is injected as a bolus of 50 to 100 cc of contrast. The nephrogenic phase is captured with a radiograph immediately after injection. In the past, tomograms were used to look for parenchymal defects, but now CT or MRI imaging is preferred. A film is taken at 5 minutes and then additional films at 5-minute intervals until the question that prompted the IVU is answered. Abdominal compression may be used to better visualize the ureters. Occasionally oblique films are used to better define the course of the ureter in the bony pelvis and to precisely differentiate ureteral stones from pelvic calcifications.

Upright films may be helpful in certain situations. In the rare case of suspected symptomatic renal ptosis, IVU can be particularly helpful (Fig. 3.2). Supine films are compared with upright films to measure the degree of ptosis. Such a comparison cannot be made with MRI or CT imaging. In the case of calyceal stones or milk of calcium stones, layering of the contrast can be helpful to evaluate the anatomy of the calyx harboring the stones.

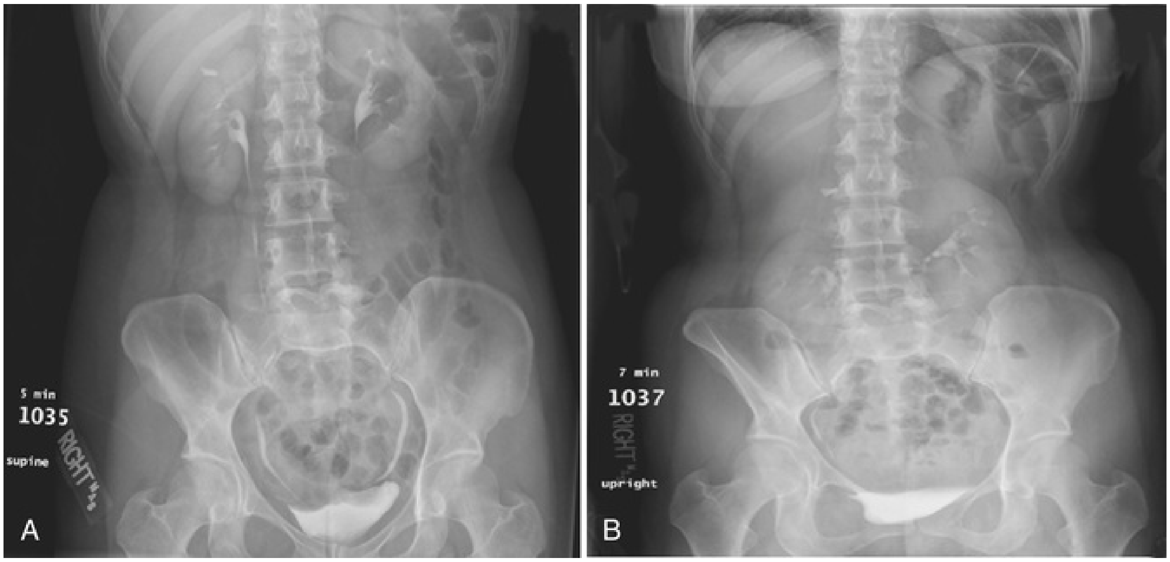

FIG. 3.2 Intravenous excretory urogram (IVU) in a 40-year-old woman with the complaint of a mobile mass in the right lower quadrant with standing associated with bilateral flank and back pain that resolved in the supine position. (A) Supine IVU shows kidneys in the normal position, with normal ureters and proximal collecting systems. (B) Standing film shows significant displacement of both kidneys with the right kidney moving onto the pelvis as described by the patient.

Postvoid films are obtained to evaluate the presence of outlet obstruction, prostate enlargement, and bladder-filling defects, including stones and urothelial cancers.

Indications

1. Demonstration of the renal collecting systems and ureters
2. Investigation of the level of ureteral obstruction
3. Intraoperative opacification of collecting system during extracorporeal shock wave lithotripsy or percutaneous access to the collecting system
4. Demonstration of renal function during emergent evaluation of unstable patients
5. Demonstration of renal and ureteral anatomy in special circumstances (e.g., ptosis, after transureteroureterostomy, and after urinary diversion)

Plain Abdominal Radiography

The plain abdominal radiograph is a conventional radiography study, which is intended to display the KUB. The plain abdominal radiograph may be employed (1) as a primary study or (2) as a scout film in anticipation of contrast media. Plain films are widely used in the management of renal calculus disease. Plain radiography is also useful in evaluation of the trauma patient because it can be performed as a portable study in the trauma unit. Secondary findings on plain radiography such as rib fractures, fractures of the transverse processes of the vertebral bodies, and pelvic fractures may indicate serious associated urologic injuries.

Technique

An abdominal plain radiograph is obtained with the patient in the supine position, using an anterior to posterior exposure. The study typically includes that portion of the anatomy from the level of the diaphragm to the inferior pubic symphysis. It may occasionally be necessary to make two exposures to cover the desired anatomic field. Depending on the indication for the study oblique films are obtained to clarify the position of structures in relation to the urinary tract. If small bowel obstruction or free peritoneal air is suspected, upright films will be obtained.

Indications

1. Preliminary film in anticipation of contrast administration
2. Assessment of the presence of residual contrast from a previous imaging procedure
3. Pre- and post-treatment assessment of renal calculus disease
4. Assessment of the position of drains and stents
5. Adjunct to the investigation of blunt or penetrating trauma to the urinary tract

Limitations

Although plain film radiography is often used in the evaluation of renal colic, it is unreliable in the demonstration of calculus disease for a variety of reasons: (1) overlying stool and bowel gas may obscure small calculi; (2) stones may be obscured by other structures such as bones or ribs (Fig. 3.3); (3) calcifications in pelvic veins or vascular structures may be confused with ureteral calculi; and (4) stones that are poorly calcified or composed of uric acid may be radiolucent. Nevertheless, plain film radiography is valuable in assessing the suitability of a patient for extracorporeal shock wave lithotripsy because the ability to identify the stone on fluoroscopy is critical to targeting. Furthermore, a KUB is very cost effective for monitoring residual stone burden after treatment (Fig. 3.4). For complex pathology of the urinary tract, plain abdominal radiography has been supplanted by axial imaging. Plain radiography has a very limited role in evaluating soft tissue abnormalities of the urinary tract.

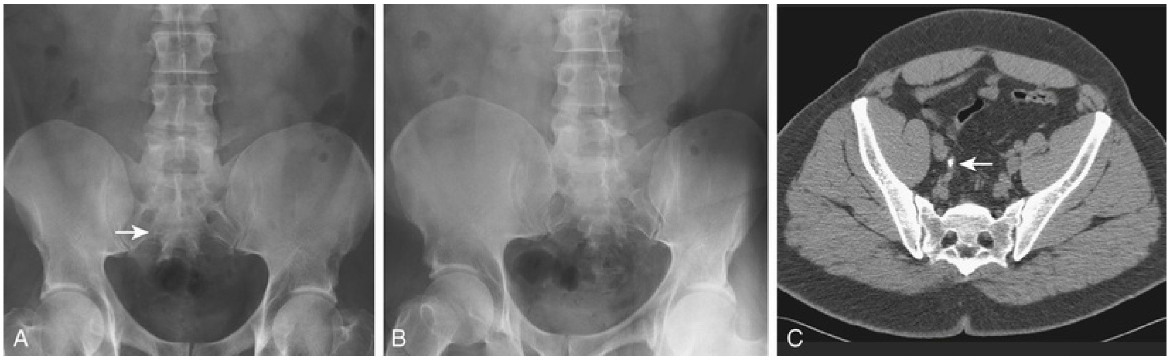

FIG. 3.3 (A) Right ureteral calculus *(arrow)* overlying the sacrum is difficult to visualize on the plain film. (B) The right posterior oblique study fails to confirm the location of the ureteral calculus. (C) CT confirms this 6-mm calculus in the right ureter at the level of the third sacral segment.

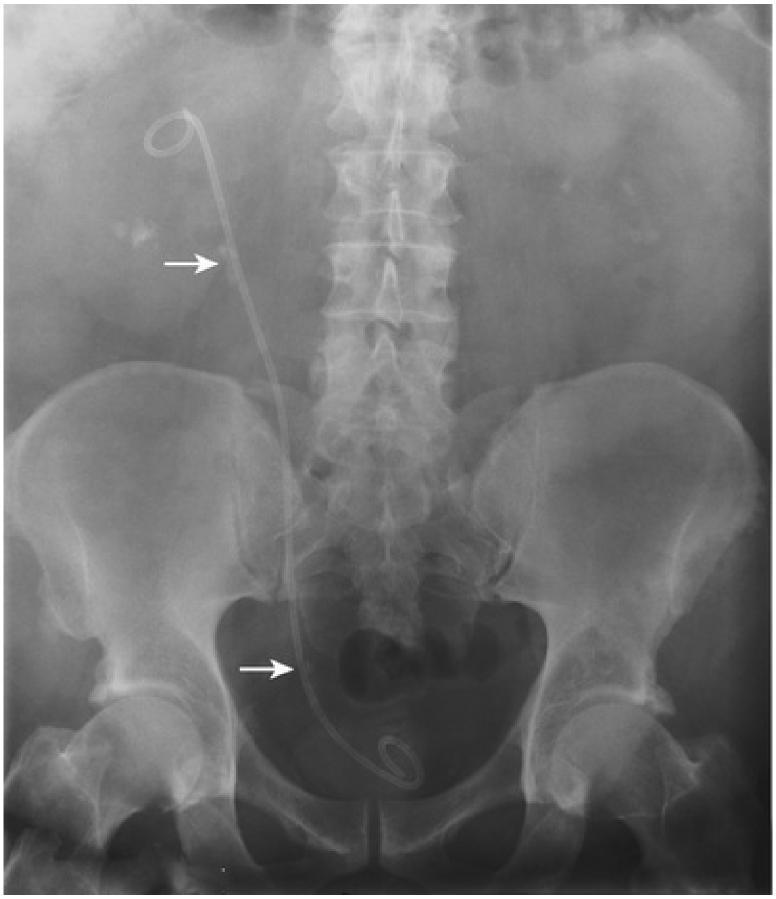

FIG. 3.4 KUB demonstrating residual stone fragments *(arrows)* adjacent to a right ureteral stent 1 week after right extracorporeal shock wave lithotripsy.

Retrograde Pyelography

Retrograde pyelograms are performed to opacify the ureters and intrarenal collecting system by the retrograde injection of contrast media. Any contrast media that can be used for excretory urography is also acceptable for retrograde pyelography. Attempts should be made to sterilize the urine before retrograde pyelography because there is a risk of introducing bacteria into the upper urinary tracts or into the bloodstream. Although many studies are able to document the presence or absence of dilation of the ureter, retrograde pyelography has the unique ability to document the normalcy of the ureter distal to the level of obstruction and to better define the extent of the ureteral abnormality.

Technique

Retrograde pyelography usually is performed with the patient in the dorsal lithotomy position. An abdominal plain radiograph (scout film) is obtained to ensure that the patient is in the appropriate position to evaluate the entire ureter and intrarenal collecting system. Cystoscopy is performed and the ureteral orifice is identified.

Contrast may be injected through either a nonobstructing catheter or an obstructing catheter. Nonobstructing catheters include whistle-tip, spiral-tip, or open-ended catheters. Use of nonobstructing catheters allows passage of the catheter into the ureter and up to the collecting system, over a guidewire if necessary. Contrast then can be introduced directly into the upper collecting system and the ureters visualized by injection of contrast as the catheter is withdrawn.

The other commonly employed method is the use of an obstructing ureteral catheter such as a bulb-tip, cone-tip, or wedge-tip catheter. These catheters are inserted into the ureteral orifice and then pulled back against the orifice to effectively obstruct the ureter. Contrast is then injected to opacify the ureter and intrarenal collecting system. Depending on the indication for the study, it is useful to dilute the contrast material (to 50% or less) with sterile fluid. This prevents subtle filling defects in the collecting system or ureter from being obscured. Care should be taken to evacuate air bubbles from the syringe and catheter before injection. Such air bubble artifacts could be mistaken for stones or tumors.

After air is expelled from the catheter into the bladder, the ureteral orifice is intubated. Contrast is injected slowly, usually requiring from 5 to 8 cc to completely opacify the ureter and intrarenal collecting system in adults (Fig. 3.5). More or less contrast may be required depending on the size of the patient and the capaciousness of the collecting system. Limited use of fluoroscopy while injecting helps prevent overdistension of the collecting system and reduces the risk of extravasation of contrast.

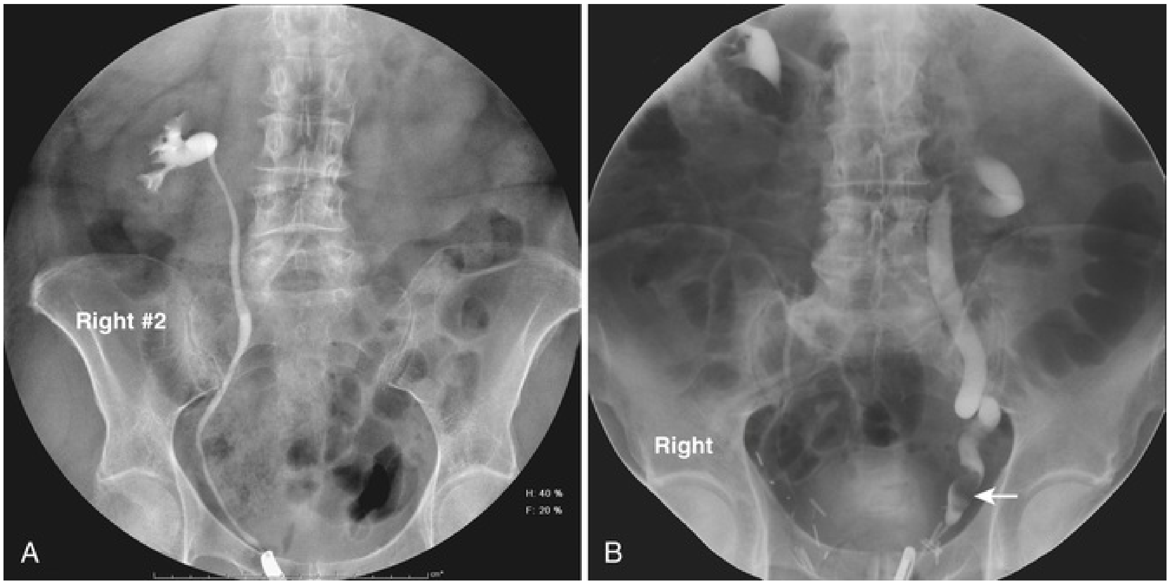

FIG. 3.5 (A) Right retrograde pyelogram performed using an 8-Fr cone-tipped ureteral catheter and dilute contrast material. The ureter and intrarenal collecting system are normal. (B) Left retrograde pyelogram using an 8-Fr cone-tipped ureteral catheter. A filling defect in the left distal ureter *(arrow)* is a low-grade transitional cell carcinoma. The ureter demonstrates dilation, elongation, and tortuosity, the hallmarks of chronic obstruction.

Historically, when a retrograde pyelogram consisted of a series of radiographs taken at intervals, it was important to document various stages of filling and emptying of the ureter and collecting systems. Because of peristalsis the entire ureter will often not be seen on any given static exposure or view. With current equipment, including tables that incorporate fluoroscopy, it is possible to evaluate the ureter during peristalsis in real time, thus reducing the need for static image documentation. Documentary still images or “spot films” may be saved for future comparison. Urologists interpret retrograde pyelograms in real time as they are performed.

Indications

1. Evaluation of congenital ureteral obstruction
2. Evaluation of acquired ureteral obstruction
3. Elucidation of filling defects and deformities of the ureters or intrarenal collecting systems
4. Opacification or distention of collecting system to facilitate percutaneous access
5. In conjunction with ureteroscopy or stent placement
6. Evaluation of hematuria
7. Surveillance of transitional cell carcinoma
8. In the evaluation of traumatic or iatrogenic injury to the ureter or collecting system

Limitations

Retrograde pyelography may be difficult in cases in which the bladder is involved with diffuse inflammation or neoplastic changes, especially when bleeding is present. Identification of the ureteral orifices may be facilitated by the intravenous injection of indigotindisulfonate sodium or methylene blue in such cases. Changes associated with bladder outlet obstruction may result in angulation of the intramural ureters. This may make cannulation with an obstructing catheter difficult. Attempts to cannulate the ureteral orifice may result in trauma to the ureteral orifice and extravasation of contrast material into the bladder wall. The potential for damage to the intramural ureter must be weighed against the potential information to be obtained by the retrograde pyelogram.

Complications

Backflow occurs during retrograde pyelography when contrast is injected under pressure and escapes the collecting system. Contrast may escape the collecting system by one of four routes: **Pyelotubular backflow** occurs when contrast fills the distal collecting ducts producing opacification of the medullary pyramids (Fig. 3.6A). **Pyelosinus backflow** occurs when a tear in the calyces at the fornix allows contrast to leak into the renal sinus (Fig. 3.6B). **Pyelolymphatic backflow** is characterized by opacification of the renal lymphatic channels (Fig.

3.6C). **Pyelovenous backflow** is seen when contrast enters the venous system, resulting in visualization of the renal vein.

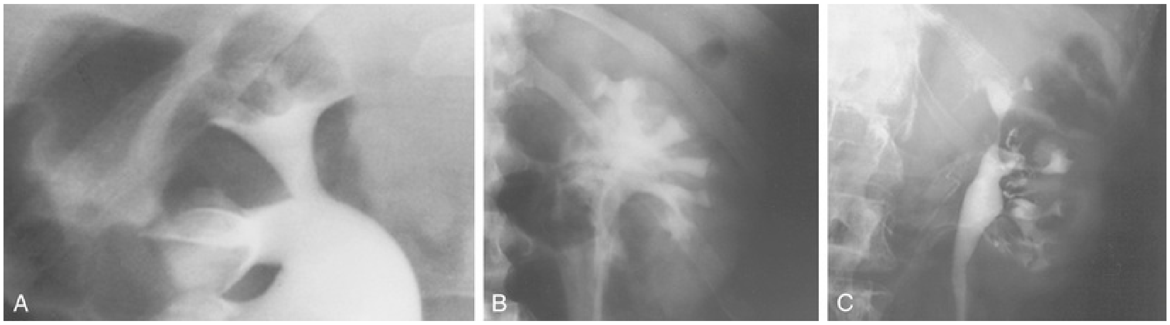

FIG. 3.6 Patterns of backflow during retrograde pyelography. (A) Pyelotubular backflow. (B) Pyelosinus backflow. (C) Pyelolymphatic backflow.

Although backflow does not usually cause measurable clinical harm, the potential implications of backflow include (1) introduction of bacteria from infected urine into the vascular system and (2) the absorption of contrast media, which could result in adverse reactions in susceptible patients. It has been demonstrated that the risk of significant urinary tract infection is only about 10% and the risk of sepsis is low when antibiotic prophylaxis therapy is administered before endoscopic procedures (including retrograde pyelography) (Christiano et al., 2000). Although contrast reactions are rare with retrograde pyelography, they have been reported (Johenning, 1980; Weese et al., 1993). In patients with documented severe contrast allergy, prophylactic pretreatment may be appropriate. In those patients considered at risk, care should be taken to inject under low pressures to minimize the probability of backflow and absorption of the contrast into the vasculature system.

Loopography

Loopography is a diagnostic procedure performed in patients who have undergone urinary diversion. Historically the term “loopogram” has been associated with ileal conduit diversion but may be used in reference to any bowel segment serving as a urinary conduit. When imaging patients with a continent diversion involving a reservoir or neobladder, “pouch-o-gram” would be more accurately descriptive. Because an ileal conduit urinary diversion usually has freely refluxing ureterointestinal anastomoses, the ureters and upper collecting systems may be visualized. In other forms of diversion, the ureterointestinal anastomoses may be purposely nonrefluxing. In such circumstances, when opacification of the upper urinary tract is desirable, antegrade ureteral imaging such as IVU, CT, or MR urography or antegrade nephrostography may be required. When the patient has compromised renal function or is allergic to iodinated contrast material, loopogram can be performed with a low risk of systemic absorption (Hudson et al., 1981).

Technique

The patient is positioned supine. An abdominal plain radiograph is obtained before the introduction of contrast material (Fig. 3.7A). A commonly employed technique is to insert a small-gauge catheter into the ostomy of the loop, advancing it just proximal to the abdominal wall fascia. The balloon on such a catheter can then be inflated to 5 to 10 cc with sterile water. By gently introducing contrast through the catheter, the loop can be distended, usually producing bilateral reflux into the upper tracts. Oblique films should be obtained to evaluate the entire length of the loop (see Fig. 3.7). Because of the angle at which many loops are constructed, a traditional anteroposterior (AP) view often shows a foreshortened loop and could miss a substantial pathology. A drain film should be obtained (see Fig. 3.7). This may demonstrate whether there is obstruction of the conduit.

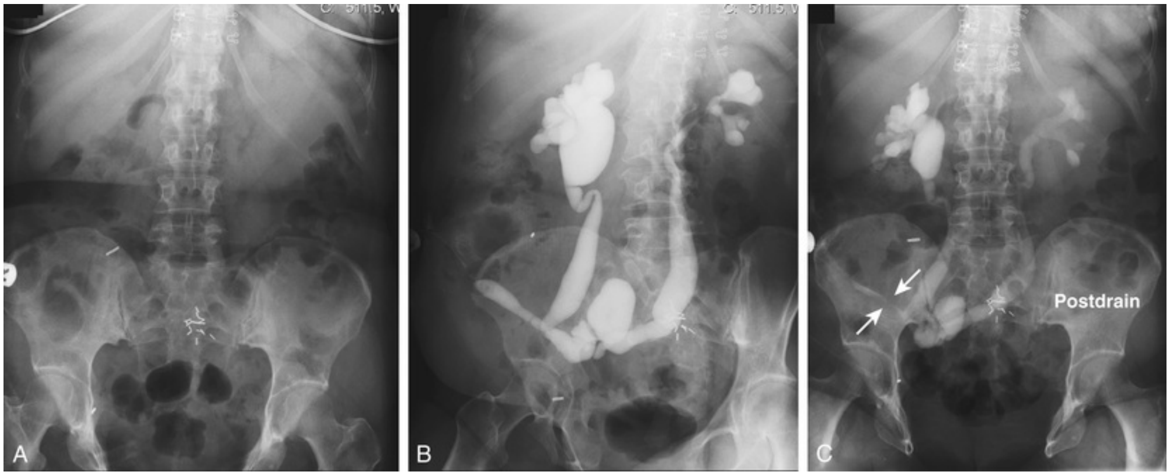

FIG. 3.7 Loopogram in a patient with epispadius/exstrophy and ileal conduit urinary diversion. The plain film (A) shows wide diastasis of the pubic symphysis. After contrast administration via a catheter placed in the ileal conduit, free reflux of both ureterointestinal anastomoses is demonstrated (B). (C) A postdrain radiograph demonstrates persistent dilation of the proximal loop indicating mechanical obstruction of the conduit *(arrows).*

Indications

1. Evaluation of infection, hematuria, renal insufficiency, or pain after urinary diversion
2. Surveillance of upper urinary tract for obstruction
3. Surveillance of upper urinary tract for urothelial neoplasia
4. Evaluation of the integrity of the intestinal segment or reservoir

Retrograde Urethrography

A retrograde urethrogram is a study meant to evaluate the anterior and posterior urethra. Retrograde urethrography may be particularly beneficial in demonstrating the total length of a urethral stricture, which cannot be negotiated by cystoscopy. Retrograde urethrography also demonstrates the anatomy of the urethra distal to a stricture, which may not be assessable by voiding cystourethrography. Retrograde urethrography may be performed in the office or in the operating room before performing visual internal urethrotomy or formal urethroplasty.

Technique

A plain film radiograph is obtained before injection of contrast. The patient usually is positioned slightly obliquely to allow evaluation of the full length of urethra. The penis is placed on slight tension. A small catheter may be inserted into the fossa navicularis with the balloon inflated to 2 cc with sterile water. Contrast then is introduced via a catheter-tipped syringe. Alternatively, a penile clamp (e.g., Brodney clamp) may be used to occlude the urethra around the catheter (Fig. 3.8).

FIG. 3.8 Normal retrograde urethrogram demonstrating (A) the balloon technique for retrograde urethrography, (B) Brodney clamp *(arrowhead)* technique; note the bulbar urethral stricture *(arrow)*, and (C) normal structures of the male urethra.

Indications

1. Evaluation of urethral stricture disease

    a. Location of stricture
    b. Length of stricture
2. Assessment for foreign bodies
3. Evaluation of penile or urethral penetrating trauma
4. Evaluation of traumatic gross hematuria

Static Cystography

Static cystography is employed primarily to evaluate the structural integrity of the bladder. The shape and contour of the bladder may give information about neurogenic dysfunction or bladder outlet obstruction. Filling defects such as tumors and stones may be appreciated.

Technique

The patient is positioned supine. A plain radiograph is performed to evaluate for stones and residual contrast and to confirm position and technique. The bladder is filled under gravity with 200 to 400 cc of contrast depending on bladder size and patient comfort. Adequate filling is important to demonstrate intravesical pathology or bladder rupture. Oblique films should be obtained because posterior diverticula or fistulae may be obscured by the full bladder. A postdrainage film completes the study (Fig. 3.9).

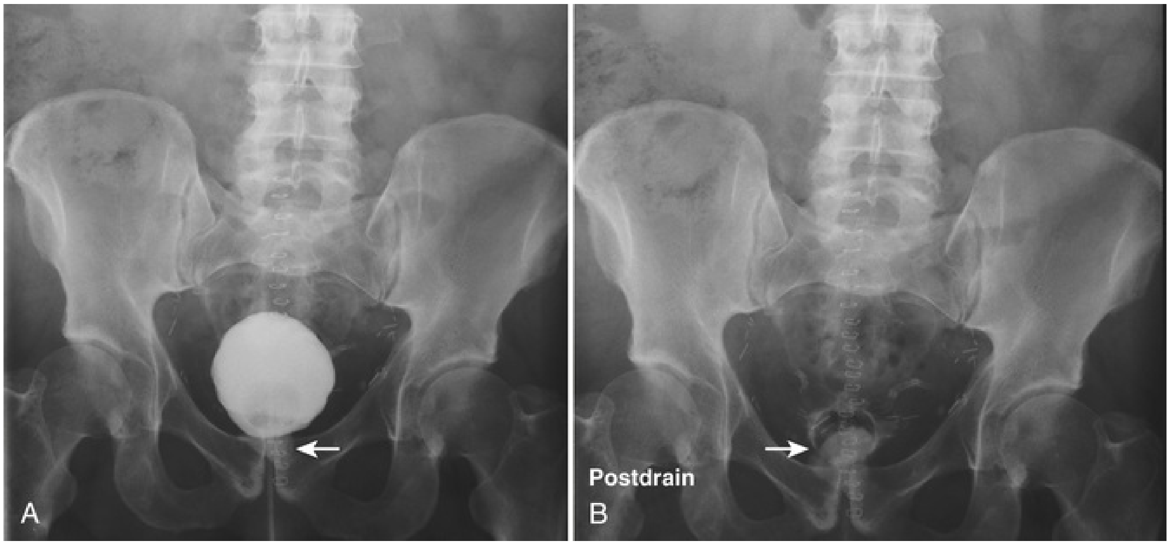

FIG. 3.9 The patient has undergone radical retropubic prostatectomy. (A) During bladder filling, contrast is seen adjacent to the vesicoureteral anastomoses *(arrow).* (B) The postdrain film clearly demonstrates a collection of extravasated contrast *(arrow).*

Indications

1. Evaluation of intravesical pathology
2. Evaluation of bladder diverticula
3. Evaluation of inguinal hernia involving the bladder
4. Evaluation of colovesical or vesicovaginal fistulae
5. Evaluation of bladder or anastomotic integrity after surgical procedure
6. Evaluation of blunt or penetrating trauma to the bladder

Limitations

Abdominal and pelvic CT are so commonly used in the evaluation of blunt or penetrating trauma to the abdomen that CT cystography is often performed in conjunction with the trauma evaluation. However, studies have shown that conventional static cystography is as sensitive as CT cystography in detecting bladder rupture (Broghammer and Wessells, 2008; Quagliano et al., 2006).

Voiding Cystourethrogram

A voiding cystourethrogram (VCUG) is performed to evaluate the anatomy and physiology of the bladder and urethra. The study provides valuable information regarding the posterior urethra in pediatric patients. VCUG has long been used to demonstrate vesicoureteral reflux.

Technique

The study may be performed with the patient supine or in a semi-upright position using a table capable of bringing the patient into the full upright position. A preliminary pelvic plain radiograph is obtained. In children, a 5- to 8-Fr feeding tube is used to fill the bladder to the appropriate volume. Patient comfort should be taken into account when determining the appropriate volume. In the adult population a standard catheter may be placed and the bladder filled to 200 to 400 cc. The catheter is removed and a film is obtained. During voiding, AP and oblique films are obtained. The bladder neck and urethra may be evaluated by fluoroscopy during voiding. Bilateral oblique views may demonstrate low-grade reflux, which cannot be appreciated on the AP film. In addition, oblique films demonstrate bladder or urethral diverticula, which are not always visible in the straight AP projection. Postvoiding films should be performed (Fig. 3.10).

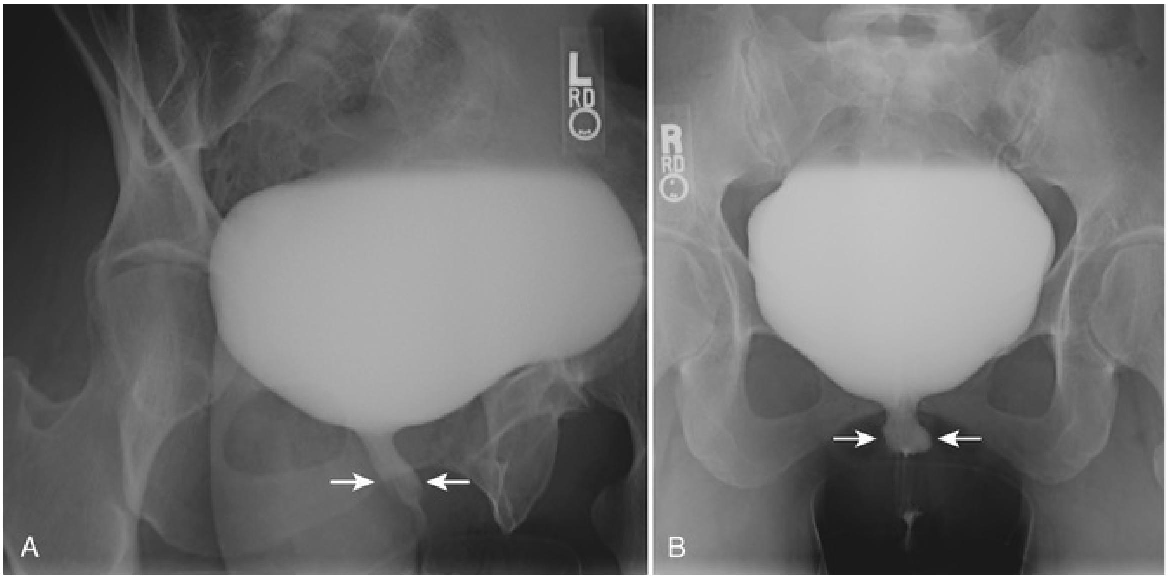

FIG. 3.10 **A voiding cystourethrogram performed for the evaluation of recurrent urinary tract infection in this female patient.** (A) An oblique film during voiding demonstrates thickening of the midureteral profile *(arrows).* (B) After interruption of voiding a ureteral diverticulum is clearly visible extending posteriorly and to the left of the midline *(arrows).*

Indications

1. Evaluation of structural and functional bladder outlet obstruction
2. Evaluation of reflux
3. Evaluation of the urethra in males and females

Limitations

This study requires bladder filling using a catheter. This may be traumatic in children and difficult in some patients with anatomic abnormalities of the urethra or bladder neck. Filling of the bladder may stimulate bladder spasms at low volumes, and some patients are unable to hold adequate volumes for investigation. **Bladder filling in patients with spinal cord injuries higher than T6 may precipitate autonomic dysreflexia** (Barbaric, 1976; Fleischman and Shah, 1977; Linsenmeyer et al., 1996).

Nuclear Scintigraphy

Radionuclide imaging is the procedure of choice to evaluate renal obstruction and function. It is very sensitive to changes that induce focal or global changes in kidney function. Because neither gadolinium or iodinated intravenous contrast agents are used, scintigraphy does not damage the kidney, has no lingering toxicity, results in minimal absorbed radiation, and is free from allergic reactions. Compared with other diagnostic imaging studies such as retrograde pyelogram, renal scintigraphy is noninvasive, has minimal risk and minimal discomfort, and allows determination of the function of the kidney.

Once the agent is intravenously injected, gamma scintillation cameras measure radiation emitted from the radioisotope and digital work stations gather, process, and display the information. There is an extensive list of radiopharmaceuticals used for renal scintigraphy. This section is limited to those agents most commonly used in urologic practice.

Technetium^{99m}–diethylenetriamine pentaacetic acid (^{99m}Tc-DTPA) is primarily a glomerular filtration agent (Gates, 2004; Peters, 1998). It is most useful for evaluation of obstruction and renal function. Because it is excreted through the kidney and dependent on GFR, it is less useful in patients with renal failure because impaired GFR may limit adequate evaluation of the collecting system and ureters. It is readily available and relatively inexpensive (Klopper et al., 1972).

Technetium^{99m}-dimercaptosuccinic acid (^{99m}Tc-DMSA) is cleared by filtration and secretion.

^{99m}Tc-DMSA localizes to the renal cortex with very little accumulation in the renal papilla and medulla (Lin et al., 1974). Therefore it is most useful for identifying cortical defects or ectopic or abhorrent kidneys. With these properties, ^{99m}Tc-DMSA can distinguish a benign functioning abnormality in the kidney from a space-occupying malignant lesion, which would not have normal renal function. No valuable information on the ureter or collecting system can be obtained with ^{99m}Tc-DMSA but remains a standard for renal cortical imaging.

Technetium^{99m}-mercaptoacetyltriglycine (^{99m}Tc-MAG3) is an excellent agent for imaging because of its photon emission, 6-hour half-life, and ease of preparation. It is cleared mainly by tubular secretion (Fritzberg et al., 1986). A small amount, approximately 10%, of MAG3 is excreted by extrarenal means, and most of this is hepatobiliary excretion (Eshima et al., 1990; Itoh, 2001). Because it is bound extensively to protein in plasma, it is limited in its ability to measure GFR but is an excellent choice for patients with renal insufficiency and urinary obstruction. The tracer is well suited for evaluation of renal function and diuretic scintigraphy. It is also an excellent tracer to evaluate renal plasma flow.

Diuretic Scintigraphy

Nuclear medicine imaging plays a crucial role unmet by CT, MRI, or ultrasound in the diagnosis of upper tract obstruction, and its unique characteristics provide noninvasive information regarding dynamic renal function. The diuretic renal scan using ^{99m}Tc-MAG3 can provide differential renal function and clearance time comparing right and left kidneys, which is pivotal in patient management. The initial phase is the flow phase, in which 2-second images are gathered for 2 minutes and then 1-second images for 60 seconds. The flow phase shows renal uptake, background clearance, and abnormal vascular lesions, which may indicate arteriovenous malformations, tumors, or active bleeding. In the second phase, the renal phase, time to peak uptake is typically between 2 and 4 minutes. The renal phase is the most sensitive indicator of renal dysfunction; 1-minute images are taken for 30 minutes. In the final phase, the excretory phase, 1-minute images are taken for 30 minutes. **A diuretic (usually furosemide 0.5 mg/kg) is administered when maximum collecting system activity is visualized. The $T_{1/2}$ is the time it takes for collecting system activity to decrease by 50% from that at the time of diuretic administration. This is highly technician dependent because the diuretic must be given when the collecting system is displaying maximum activity. Transit time through the collecting system in less than 10 minutes is consistent with a normal, nonobstructed collecting system. $T_{1/2}$ of 10 to 20 minutes shows mild to moderate delay and may be a mechanical obstruction. The patient's perception of pain after diuretic administration can be helpful for the treating urologist to consider when planning surgery in the patient with middle to moderate obstruction. A $T_{1/2}$ of greater than 20 minutes is consistent with a high-grade obstruction. The level of obstruction usually can be determined as can abnormalities such as ureteral duplication** (Ell and Gambhir, 2004). A normal renal scan is shown in Fig. 3.11.

FIG. 3.11 (A) Technetium^{99m}-mercaptoacetyltriglycine (^{99m}Tc-MAG3) perfusion images demonstrate normal, prompt, symmetric blood flow to both kidneys. (B) Perfusion time-activity curves demonstrating essentially symmetric flow to both kidneys. Note the rising curve typical of ^{99m}Tc-MAG3 flow studies. Dynamic function images demonstrate good uptake of tracer by both kidneys and prompt visualization of the collecting systems. This renogram demonstrates prompt peaking of activity in both kidneys. The downslope represents prompt drainage of activity from the kidneys. Printout of quantitative data shows the differential renal function to be 47% on the left, 53% on the right. The normal half-life for drainage is less than 20 minutes when ^{99m}Tc-MAG3 is used. The $T_{1/2}$ is 5 min on the left and 7 min on the right, consistent with both kidneys being unobstructed.

Hepatobiliary excretion can cause false-positive readings if the area of intestinal activity or gallbladder activity is included in the area of interrogations during the study (Fig. 3.12).

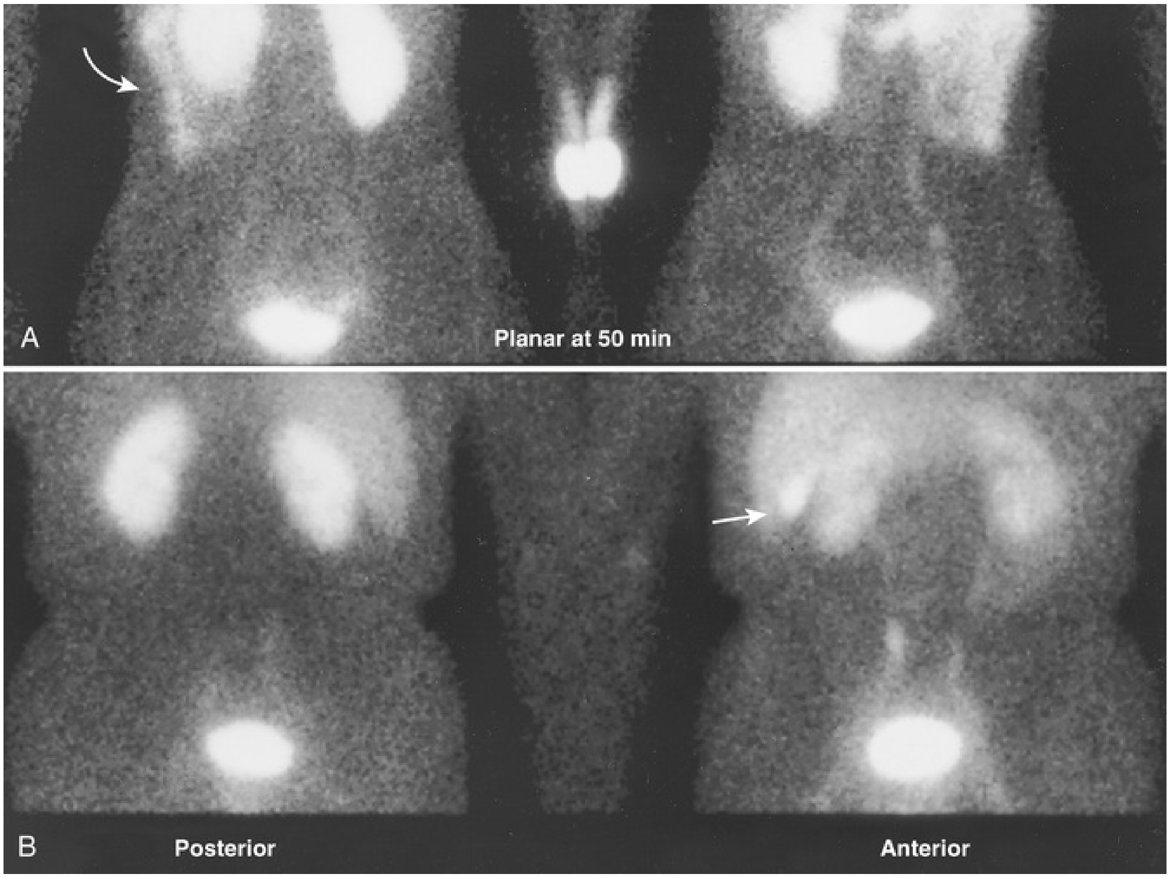

FIG. 3.12 Delayed static images in the posterior and anterior projections demonstrate intestinal activity (*arrow* in A) and gallbladder activity (*arrow* in B), reflecting a normal mode of excretion of ^{99m}Tc-MAG3. Gallbladder activity, in particular, can cause false-positive interpretation when it overlies activity in the renal collecting system or is inappropriately included in the area of interrogation. Liver activity is variable and tends to be more pronounced in children and patients with renal insufficiency.

The diuretic renal scan is another imaging study in which communication with the interpreting physician is vital for correct performance of the test as well as appropriate interpretation. For example, there are times when patients with unilateral or bilateral ureteral stents are sent for diuretic scintigraphy to determine differential renal function. If a bladder catheter is not placed and is open to drainage during the diuretic renal scan, the radiopharmaceutical excreted from the healthy kidney may wash up into or back flow via the ureteral stent into the stented kidney, giving the false-positive appearance to have more function than is physiologically present. This false-positive test may lead to inappropriately reconstructing a kidney that has little or insufficient function.

Nuclear Medicine in Urologic Oncology

Whole-Body Bone Scan

Conventional radionuclide imaging in urologic malignancy has long been the standard for detecting bone metastasis. The whole-body bone scan, or skeletal scintigraphy, is the most sensitive method for detecting bone metastasis (Narayan et al., 1988). A “positive” bone scan is not specific for cancer and may require plain film radiography, CT, or MRI to confirm as well as correlation with prior history of bone fractures, trauma, surgery, or arthritis. In patients with diffuse metastatic bone involvement, the bone scan can be mistaken for normal because there is uniformly increased uptake in the bony structures (Kim et al., 1991).

Positron Emission Tomography

One of the most rapidly changing areas of imaging in urologic oncology is in the use of PET/CT and PET/MRI. Depending on the radiotracer used, PET offers diagnostic information based on glucose, choline, or amino acid metabolism and has been applied to imaging tumor cell proliferation and tissue hypoxia in urologic malignancies. PET with 2-[^{18}F]fluoro-2-deoxy-D-glucose (^{18}F-FDG), available since the late 1990s, exploits the increased use and high uptake of glucose by malignant cells and provides new imaging opportunities in urology. The radiopharmaceutical most commonly used for PET in oncology is ^{18}F-FDG, an analog of glucose that is preferentially taken up and trapped inside malignant cells. For more than a decade, integrated PET/CT, in which a full-ring-detector clinical PET scanner and multidetector-row helical CT scanner are combined, has made it possible to acquire metabolic and anatomic imaging data using a single device in a single diagnostic session and provides precise anatomic localization of suspicious areas of increased ^{18}F-FDG uptake.

In urologic oncology, the use of ^{18}F-FDG has been limited by low tumor uptake and physiologic excretion of ^{18}F-FDG through the urinary system masking ^{18}F-FDG uptake by the primary urologic carcinoma. **The diagnostic performance of FDG-PET is hampered by the renal excretion of FDG and by the low metabolic activity often seen in tumors such as prostate cancer. However, new PET tracers, including radiolabeled choline, acetate, and others may offer alternatives with improved diagnostic abilities. There is consistent evidence that FDG-PET provides important diagnostic**

information in detecting metastatic and recurrent testicular germ cell tumors, and it may offer additional information in the staging and restaging of bladder and renal cancer (Kitajima et al., 2014, 2016; Powles et al., 2011; Rioja et al., 2010).

Molecular imaging with PET is showing promise to individualize the surgical and medical care of urologic oncology patients. PET provides unique insights into molecular pathways of diseases. PET using [F-18]-fluorodeoxyglucose (FDG) has gained increasing acceptance for the diagnosis, staging, and treatment monitoring of some genitourinary (GU) tumor types.

Kidney Cancer

Contrast-enhanced CT provides accurate information for detection and staging of renal cell carcinoma (RCC). Extrarenal metastatic disease is more easily detected by ^{18}F-FDG PET/CT and is useful for staging, restaging, and treatment of advanced RCC. A meta-analysis of 14 studies included 517 patients, demonstrated a pooled sensitivity of ^{18}F-FDG PET or PET/CT to be 79% for intrarenal tumors and 84% for extrarenal metastases, and that ^{18}F-FDG PET/CT increased the pooled sensitivity to 91% (Ferda et al., 2013; Wang et al., 2012). Other investigators have evaluated the clinical impact of ^{18}F-FDG PET/CT for restaging renal cancer in 104 patients after surgery and demonstrated that the sensitivity and specificity were 74% and 80%, respectively (Alongi et al., 2016).

Bladder Cancer

For localized bladder cancer, ^{18}F-FDG PET has not been widely used because its physiologic activity excreted through the urinary system interferes with visualization of the primary bladder cancer and locoregional lymph nodes (LNs). A meta-analysis showed that the sensitivity and specificity of ^{18}F-FDG PET/CT for detecting bladder cancer was 80% (95% CI 71%–87%) and 84% (95% CI 69%–93%), respectively (Wang et al., 2014).

In patients with metastatic disease ^{18}F-FDG PET/CT is useful for staging and restaging (detection of metastatic lesions) of bladder cancer. A systematic review and meta-analysis of 6 studies involving 236 patients showed that the pooled sensitivity and specificity for staging and restaging (metastatic lesions) were 82% (95% CI 0.72–0.89) and 89% (95% CI 0.81–0.95), respectively (Lu et al., 2012).

Prostate Cancer

Many different PET tracers are being actively investigated for use in PET/CT imaging for prostate cancer. It is well known that the ability of ^{18}F-FDG PET to detect cancer is based on increased expression of cellular membrane glucose transporter 1 (GLUT1) and enhanced hexokinase II enzyme activity within tumor cells. Preclinical studies have examined the expression of GLUT1 in prostate cancer cell lines and found that it is higher in those that are poorly differentiated in comparison with well-differentiated hormone-sensitive cell lines (Jadvar et al., 2005). This suggests that GLUT1 transporter expression increases with increasing disease grade and may explain the higher ^{18}F-FDG accumulation in castration-resistant than in castration-sensitive tumors and the modulatory effect of androgen on the glucose metabolism of castration-sensitive tumors.

^{18}F-FDG PET/CT is of limited value for detection and localization of primary prostate cancer and initial staging of disease because most primary tumors are slow growing, well differentiated, multiple, and small, with tumor uptake levels that can overlap with those of normal tissue, prostatitis, or benign prostatic hyperplasia (BPH).

^{11}C-choline and ^{18}F-fluorocholine are well-established tracers routinely employed at some PET centers for imaging of prostate cancer. Focal choline uptake in the prostate could arouse suspicion of prostate cancer, but nonmalignant causes, such as high-grade prostatic intraepithelial neoplasia, prostatitis, BPH, and normal tissue, also can be sources of false-positive focal activity (Reske et al., 2006).

In the largest preoperative series (n = 210) of intermediate- and high-risk patients who had undergone radical prostatectomy (RP) with surgical LN dissection, the sensitivity and specificity for detection of pelvic LN metastases were 73% and 88%, with a node-based sensitivity and specificity of 56% and 94%, respectively (Poulsen et al., 2012).

Choline PET/CT is a useful modality for detection of bone metastasis. In a patient-based analysis of patients with prostate-specific antigen (PSA) progression after primary treatment, comparing ^{11}C-choline PET/CT and bone scintigraphy for detection of bone metastasis, ^{11}C-choline PET/CT had better sensitivity and specificity (Picchio et al., 2012). Choline PET/CT can be useful in restaging of biochemically recurrent prostate cancer, particularly when the PSA level becomes significantly elevated. Many reports have discussed the usefulness of choline PET/CT for detecting sites of recurrence in patients with

PSA failure, and choline PET/CT is employed routinely for this purpose at a number of PET centers (Picchio et al., 2012).

^{11}C-acetate PET/CT has also been used for identification of recurrent prostate cancer in the setting of PSA failure, with a reported sensitivity of 59% to 83% (Kitajima et al., 2014).

PET with ^{18}F-sodium fluoride (^{18}F-NaF) is a highly sensitive radiotracer for skeletal metastases whose uptake reflects the increased regional blood flow, and bone turnover in malignant bone lesions has been reported to be more sensitive for detection of skeletal metastases than bone scintigraphy (Even-Sapir et al., 2006). The combined administration of ^{18}F-NaF and ^{18}F-FDG in a single PET/CT scan for cancer detection has been advocated for detection of extraskeletal and skeletal lesions. It has been reported that ^{18}F-NaF/FDG PET/CT is superior to whole-body MRI and bone scintigraphy for evaluating the extent of skeletal disease (Minamimoto et al., 2015).

Prostate-specific membrane antigen (PSMA) has been used as a relevant target for imaging of prostate cancer. PSMA is a cell-surface protein expressed at higher levels in prostate carcinoma tissue than in other tissues, and its expression is associated with tumor aggressiveness, androgen independence, metastatic disease, and disease recurrence. Mainly available in Europe, PSMA-targeting ligands have been labeled with ^{68}Ga for PET imaging, and this approach shows some promise for detection of prostate carcinoma recurrence. The use of ^{68}Ga-PSMA PET/CT in 248 patients (PSA 0.2–59.4 ng/mL, median 1.99 ng/mL) treated with RP demonstrated that the patient-based detection rate was 89.5%; the detection rates for PSA levels of ≥2, 1 to <2, 0.5 to <1, and 0.2 to <0.5 ng/mL were 96.8%, 93.0%, 72.7%, and 57.9%, respectively. ^{68}Ga-PSMA PET/CT reveals a high degree of positivity within the clinically important range of low PSA values (<0.5 ng/mL), which in many cases can substantially influence further clinical management (Eiber et al., 2015). It has been demonstrated that ^{68}Ga-PSMA PET/CT may be superior to ^{18}F-choline PET/CT and conventional imaging modalities (bone scintigraphy and contrast-enhanced CT of the chest, abdomen, and pelvis) or identification of disease recurrence in the setting of biochemical failure (Morigi et al., 2015). Fig. 3.13 shows different PET images.

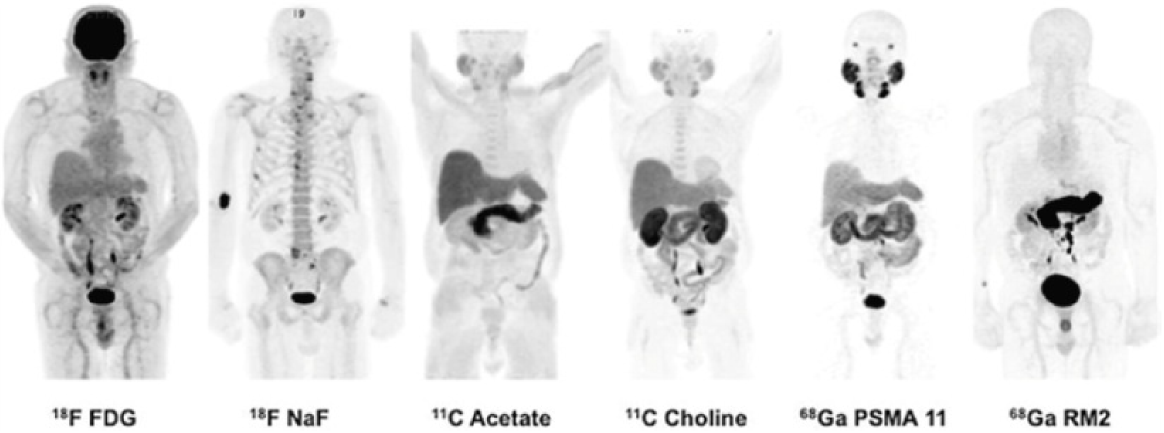

FIG. 3.13 Six different PET tracers used to evaluate an 83-year-old man with a T2b nodule and a prostate-specific antigen (PSA) level of 5.4, confirmed Gleason 5+4 prostate adenocarcinoma, and treated with intensity-modulated pelvic radiotherapy and androgen blockade. After PSA nadir of 0.11, biochemical recurrence occurred with PSA of 1.83 and negative conventional imaging. Patient was followed for 40 months under watch-and-wait strategy due to no identification of sites of recurrent disease despite increasing PSA up to 18.7 at the time of positive Ga-68 PSMA 11 and Ga-68 RM2 (both show retroperitoneal lymph nodes whereas all other studies are negative). (Image courtesy of Andrei Iagaru, MD, Stanford University.)

Adrenal Cancer

Malignant adrenal disease tends to have higher ^{18}F-FDG uptake compared with benign adrenal lesions. A meta-analysis, including 21 selected studies with a total of 1391 lesions (824 benign, 567 malignant) in 1217 patients revealed a pooled sensitivity of 97% (95% CI 93%–98%) and specificity of 91% (95% CI 87%–94%) of ^{18}F-FDG PET/CT (SUV_{max} or standard uptake ratio) for differentiating between malignant and benign adrenal disease (Boland et al., 2011). A multicenter study demonstrated that ^{18}F-FDG PET/CT showed the better diagnostic accuracy of diagnosing primary adrenal malignancy (adrenocortical carcinoma, malignant pheochromocytoma, neuroblastoma, and lymphoma) than contrast-enhanced CT (Cistaro et al., 2015). The diagnostic performance of ^{18}F-FDG PET/CT for differentiating metastatic adrenal tumors from adrenal adenoma is high (sensitivity, specificity, and accuracy are 82%, 92%, and 90%) as well as adrenal protocol CT (unenhanced early and delayed contrast-enhanced CT) and, moreover, the combination of ^{18}F-FDG PET/CT and adrenal protocol CT can improve the ^{18}F-FDG PET/CT or adrenal protocol CT diagnostic accuracy for differentiation of metastatic adrenal tumors from adrenal adenoma, reducing false-positive cases (Ardito et al., 2015; Park et al., 2014).

Testis Cancer

^{18}F-FDG PET/CT is useful for initial staging of testicular cancer and determining the viability of residual masses after completion of treatment, especially in patients with seminoma. The clinical impact of ^{18}F-FDG PET/CT for staging and restaging of testicular tumors was evaluated in 51 cases of seminoma and 70 cases of nonseminoma. PET/CT showed good sensitivity and specificity for detection of seminoma lesions (92% and 84%, respectively), but its sensitivity was lower for nonseminoma forms (77% and 95%, respectively); it influenced the clinical management of 47 out of 51 (92%) seminomas and 59 out of 70 (84%) nonseminomas (Ambrosini et al., 2014). A meta-analysis including four selected studies with a total of 130 patients evaluated the diagnostic accuracy of ^{18}F-FDG PET/CT for prediction of viable residual tumors after chemotherapy in patients with metastatic seminoma and demonstrated that it was superior to CT for determining tumor size and predicting tumor viability: sensitivity was 72% versus 63%, specificity was 92% versus 59%, positive predictive value (PPV) was 70% versus 28%, and negative predictive value (NPV) was 93% versus 86%, respectively (Müller et al., 2011). Another review and meta-analysis including nine selected studies with a total of 375 patients showed that ^{18}F-FDG PET/CT had a pooled sensitivity of 78% (95% CI: 67%–87%), a specificity of 86% (95% CI 81%–89%), a PPV of 58% (95% CI 48%–68%), an NPV of 94% (95% CI 90%–96%), and an accuracy of 84% (95% CI 80%–88%) (Treglia et al., 2014). These results mean that negative ^{18}F-FDG PET/CT findings warrant follow-up if only to avoid inappropriate subsequent treatment (surgery, chemotherapy, or radiotherapy), whereas positive ^{18}F-FDG PET/CT findings suggest a high possibility of residual seminoma, although a false-positive result cannot be excluded in view of the low PPV.

Several limitations of PET imaging for testis cancer should be noted when considering ^{18}F-FDG PET: (1) Lesions of less than 1 cm are often not detected because of the limited spatial resolution of PET. (2) Mature teratoma has variable low ^{18}F-FDG uptake or no uptake and cannot be distinguished from necrosis or fibrosis, and therefore ^{18}F-FDG PET is not recommended for characterization of residual masses after therapy for nonseminomatous germ cell cancers, which frequently harbor residual foci of mature teratoma. (3) There should be a minimum of 6 weeks between the end of chemotherapy and acquisition of an ^{18}F-FDG PET/CT scan to avoid any false-positive findings resulting from chemotherapy-induced inflammatory and granulomatous tissues or false-negative results resulting from temporary suppression of tumor cell activities (Bachner et al., 2012; Kazuhiro et al., 2016; Oechsle et al., 2008). Fig. 3.14 shows testis PET/CT before and after chemotherapy.

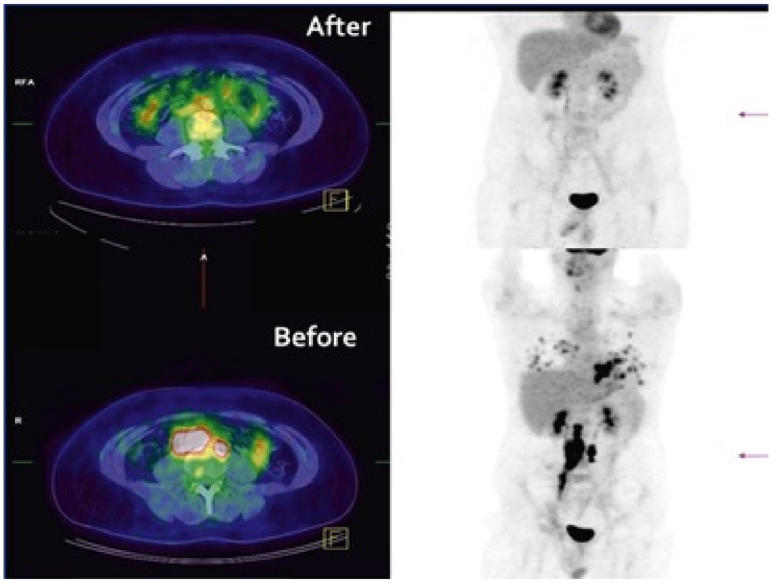

FIG. 3.14 Fluorine-18 fluorodeoxyglucose (^{18}F-FDG) PET/CT is useful for staging and restaging of seminoma in patients treated with chemotherapy. This patient presented with a right-sided seminoma with bulky right-sided retroperitoneal lymph nodes. PET/CT after chemotherapy shows no uptake in the previously positive nodal region.

Positron Emission Tomography Magnetic Resonance Imaging

There is increasing interest in the integration of PET/MRI systems because PET/MRI would have advantages over PET/CT, including improved soft-tissue contrast, the possibility of performing simultaneous instead of sequential acquisitions, and the availability of sophisticated MRI sequences (diffusion and perfusion imaging, functional MRI, and MR spectroscopy) while offering a significant decrease in radiation exposure. Its use had been demonstrated in patients with RCC, bladder cancer, prostate cancer, and pheochromocytoma, which is of foremost importance for serial follow-up and pediatric imaging (Table 3.4).

TABLE 3.4

PET Tracer in Urologic Oncology

BIOLOGIC ANALOG	PROCESS TARGETED	EFFECT
^{18}F-FDG Glucose	Glucose transporters and hexokinases	Aerobic and anaerobic glycolysis, glucose consumption
^{11}C-choline Choline	Choline kinase	Cell membrane metabolism, tumor proliferation
^{18}F-choline Choline	Choline kinase	Cell membrane metabolism, tumor proliferation
^{11}C-acetate Acetate	Tricarboxylic acid cycle and fatty acid synthase	Lipid synthesis
^{18}F-FDHT Testosterone	Androgen receptor	Measures androgen receptor
^{18}F-NaF Fluoride	Hydroxyl and bicarbonate ions of bone hydroxyapatite	Measures bone status
^{18}F-FMISO NA	Measures hypoxia	Tumor hypoxia
^{18}F-FLT NA	Thymidine kinase	Nucleic acid synthesis, tumor proliferation
^{18}F-FACBC Amino-fluorocyclobutane-carboxylic acid	Neutral A–A type amino acid uptake and protein synthesis	Protein synthesis
^{68}Ga-PSMA Prostate-specific membrane antigen	Prostate cell surface protein	Tumor aggressiveness, androgen independence

Key Points: Nuclear Scintigraphy

- During diuretic renal scan, the diuretic must be given when maximum activity is seen in the kidney.
- An elimination $T_{1/2}$ less than 10 minutes is an unobstructed system, and a $T_{1/2}$ greater than 20 minutes is consistent with high-grade obstruction.
- If ureteral stents are in place, patients undergoing diuretic renal scan should

have an unclamped bladder catheter in place during the study.

- Technetium^{99m}-mercaptoacetyl triglycerine (MAG3) is the agent of choice for diuretic renal scan to determine differential renal function and obstruction.

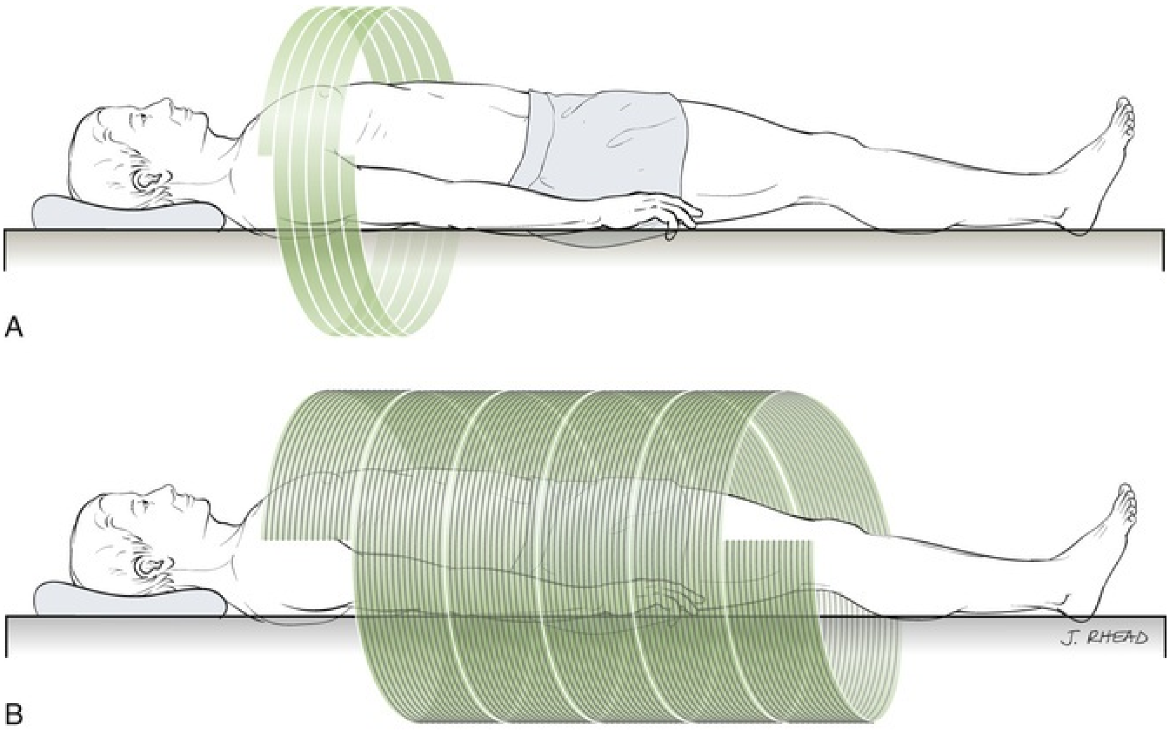
Computed Tomography

The 1979 Nobel Prize in Medicine and Physiology was awarded to Allan M. Cormack and Sir Godfrey N. Hounsfield for the development of computer-assisted tomography. Although basic principles remain the same, significant advances have resulted in the development of multidetector CT devices, improving soft-tissue detail and allowing the possibility of rapid 3D reconstruction of the entire genitourinary system.

CT has become one of the most integral parts of urologic practice, and the CT urogram (CTU) has replaced IVU as the imaging modality of choice in modern urology for the workup of hematuria, urologic malignancies, detection of kidney stones, and preoperative planning. As in the case of conventional radiographic imaging, the basis for CT imaging is the attenuation of x-ray photons as they pass through the patient. Tomography is an imaging method that produces 3D images of internal structures by recording the passage of x-rays as they pass through different body tissues. In the case of CT, a computer reconstructs cross-sectional images of the body based upon measurements of x-ray transmission through thin slices of the body tissue (Brant, 1999). A collimated x-ray beam is generated on one side of the patient and the amount of transmitted radiation is measured by a detector placed on the opposite side of the x-ray beam. These measurements are then repeated systematically while a series of exposures from different projections is made as the x-ray beam rotates around the patient. The result is production of a 3D image of internal structures in the human body by recording the passage of different energy waves through various internal structures. Data collected by the detectors are reconstructed by computerized algorithms to result in a viewable tomographic display.

There are several different imaging variables that are adjusted to allow adequate, detailed image resolution, while minimizing the time on the scanner and limiting exposure to radiation. The variable application of pitch, beam collimation, detector size, and tube voltage are used by the radiologist and imaging technologist for ideal image requisition. A detailed description of each of these variables is beyond the scope of this chapter.

Perhaps the greatest recent advancement in CT is the use of helical image acquisition techniques with multichannel or multidetectors (MDCTs). In a helical CT the patient moves through a continuously rotating gantry. The helical raw images are processed using interpolation algorithms to visualize the internal structures as sagittal, coronal, or axial reconstructed images. The “single-slice spiral CT,” introduced in 1988, had a single row of detectors and required multiple passes to visualize a small area of interrogation. The standard scanners in use today have between 64 and 320 rows of detectors, which allow the patient's entire body to be imaged during a single breath hold, with few or no motion artifacts, more precise diagnostic accuracy, increased concentration of contrast material, shorter scanning time, less radiation exposure, and significant increase in anatomic coverage with a single scan. CT scanners with 750 rows of detectors are currently being developed. For example, a 640-slice CT scanner with a gantry rotation of 0.275 seconds can image 16 cm (6.3 inches) in a single rotation with 0.5-mm slices and some scanners can capture 73 cm/s (28 inches/s), capturing all of the body's organs in a single rotation of the central x-ray–emitting gantry (Mahesh, 2002; Wang and Vannier, 1994) (Fig. 3.15).



FIG, 3.15 (A) CT scanner with a single-row detector requires five circular passes around the patient to image a small area of the patient's body. (B) With a 16-slice, multirow detector, the chest, abdomen, and pelvis can be imaged with five circular passes, easily obtained during a single breath hold. The thin slices offered by the 16-slice detector offer much greater detail of internal structures.

Readily available software is capable of complex and accurate 3D processing of CT images to recreate the urinary system. These 3D images offer improved preoperative planning, appreciation of proximity to adjacent organs, and the ability to define vasculature and improve communication with patients who can now easily see their particular pathology and better appreciate the challenges faced by their surgeon. These images are often used for printing of 3D organ models. In some complex urology cases, the segmentation and formatting of CT images to create 3D renderings can be more useful during surgery than 3D printed organs (Christiansen et al., 2018) (Fig. 3.16).

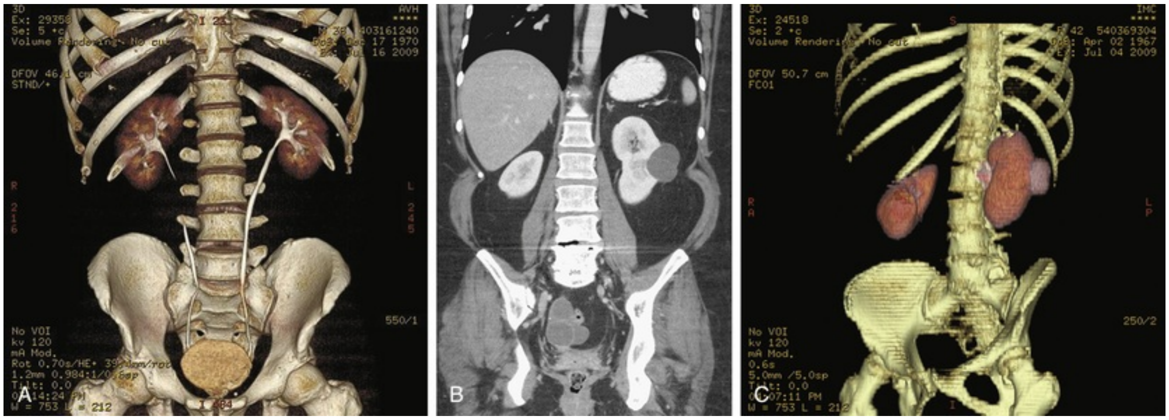


FIG. 3.16 (A) 3D colored reconstruction of the kidneys ureter and bladder from CT urogram. (B) Coronal reconstruction in a patient with a clear cell renal cell carcinoma in a complex renal cystic mass and enhancing mural nodule. (C) 3D reconstruction of the same patient with slight posterior rotation.

Dual-source CT (DSCT) is a relatively new technique used for diagnostic imaging, using two rotating tubes to acquire high- and low-voltage images, allowing tissue differentiation, visualization of tendons and ligaments, improved CT angiography, and differentiation of kidney stones based upon stone composition (Coursey, 2010). Use of DSCT helps make a reliable distinction between uric acid and calcium oxalate and between brushite and uric acid stones (Botsikas, 2013; Ferrandino, 2010).

Real-time CT fluoroscopy is available as an option on new CT imaging equipment. CT fluoroscopy gives a 3D CT image that is much more detailed and offers greater soft-tissue contrast and resolution than conventional CT. The most common use in urology is for biopsy of the kidney. CT fluoroscopy helps to overcome movement of the kidney during respiratory variation. It also has been used for fluid aspiration, drain placement, catheter placement, percutaneous cryoablation, and radiofrequency ablation of renal tumors. **One significant disadvantage of CT fluoroscopy is the increased radiation exposure to the patient and radiologist or surgeon performing the procedure** (Daly et al., 1999; Gupta et al., 2006; Keat, 2001).

The CT urogram (CTU) is an excretory urography in which the MDCT is used for imaging of the urinary tract. It is indicated in the workup of hematuria, kidney stones, renal masses, renal colic, and urothelial tumors. The CT scan examination starts with the physician's request for imaging. Radiologists around the world appreciate, from the urologist, a brief description of the question to be answered by the CT scan. Equipped with a better understanding of why the CT scan was ordered, the radiologist and the CT technician can adjust different CT variables and choose the appropriate contrast media needed to deliver a valuable report to the ordering urologist.

Urologists often request a CT evaluation of the abdomen and pelvis. An abdominal CT scan starts at the diaphragm and ends at the iliac crest. If the pelvis is to be imaged, a separate request usually is required. The pelvic CT scan begins at the iliac crest and terminates at the pubis symphysis. Intravenous contrast may be required for better delineation of soft tissue. Oral contrast is not commonly used in urology but may be helpful in certain cases to differentiate bowel from lymph nodes, scar, or tumor (Fig. 3.17).

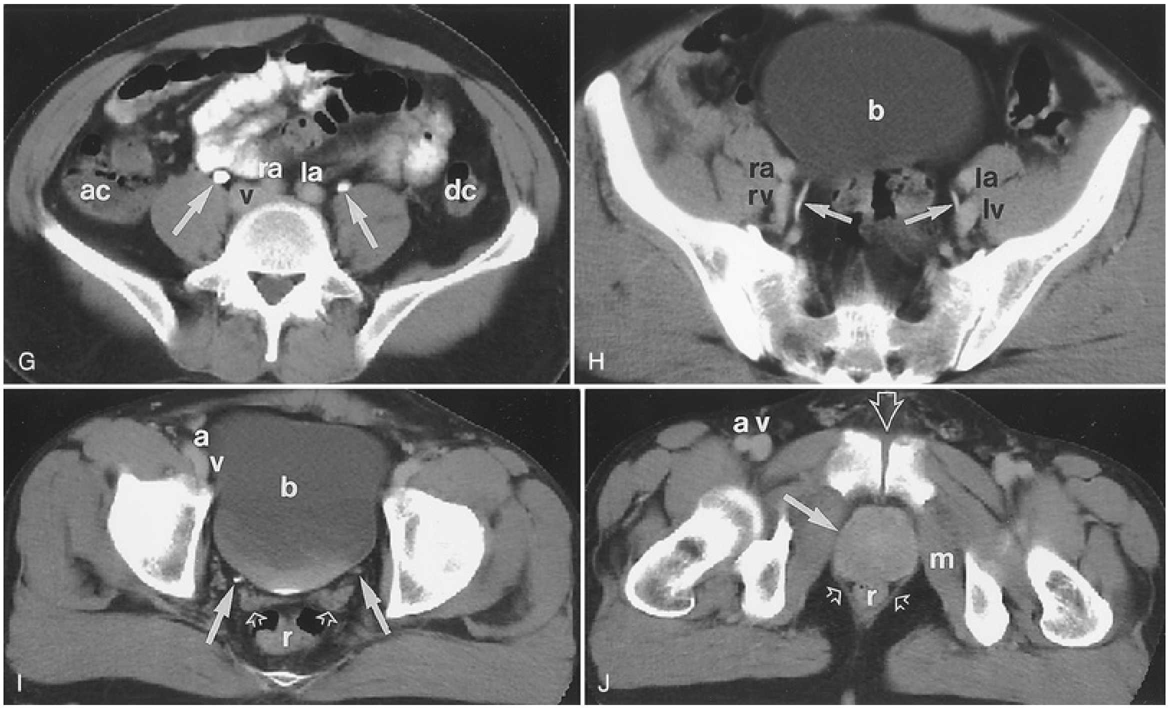

FIG. 3.17 CT of the abdomen and pelvis demonstrating normal genitourinary anatomy. (A) The adrenal glands are indicated with *arrows.* The upper pole of the right and left kidneys is indicated with *rk* and *lk,* respectively. *a,* aorta; *li,* liver; *p,* pancreas; *s,* spleen; *v,* inferior vena cava. (B) Scan through the upper pole of the kidneys. The left adrenal gland is indicated with an *arrow. a,* aorta; *c,* colon; *d,* duodenum; *li,* liver; *lk,* left kidney; *p,* pancreas; *rk,* right kidney; *v,* inferior vena cava. (C) Scan through the hilum of the kidneys. The main renal veins are indicated with *solid arrows,* and the right main renal artery is indicated with an *open arrow. a,* aorta; *c,* colon; *d,* duodenum; *li,* liver; *lk,* left kidney; *p,* pancreas; *rk,* right kidney; *v,* inferior vena cava. (D) Scan through the hilum of the kidneys slightly caudal to C. The left main renal vein is indicated with a *solid straight arrow,* and the left main renal artery is indicated with an *open arrow.* The hepatic flexure of the colon is indicated with a *curved arrow. a,* Aorta; *c,* colon; *d,* duodenum; *li,* liver; *lk,* left kidney; *p,* pancreas; *rk,* right kidney; *v,* inferior vena cava. (E) Scan through the mid to lower polar region of the kidneys. *a,* Aorta; *ac,* ascending colon; *d,* duodenum; *dc,* descending colon; *lk,* left kidney; *p,* pancreas; *rk,* right kidney; *rp,* renal pelvis; *v,* inferior vena cava. (F) CT scan obtained below the kidneys reveals filling of the upper ureters *(arrows).* The wall of the normal ureter is usually paper thin or not visible on CT. *a,* aorta; *ac,* ascending colon; *dc,* descending colon; *v,* inferior vena cava. (G) Contrast filling of the midureters *(arrows)* on a scan obtained at the level of the iliac crest and below the aortic bifurcation. *ac,* Ascending colon; *dc,* descending colon; *la,* left common iliac artery; *ra,* right common iliac artery; *v,* inferior vena cava. (H) The distal ureters *(arrows)* course medial to the iliac vessels on a scan obtained below the promontory of the sacrum. *b,* urinary bladder; *la,* left external iliac artery; *lv,* left external iliac vein; *ra,* right external iliac artery; *rv,* right external iliac vein. (I) Scan through the roof of the acetabulum reveals distal ureters

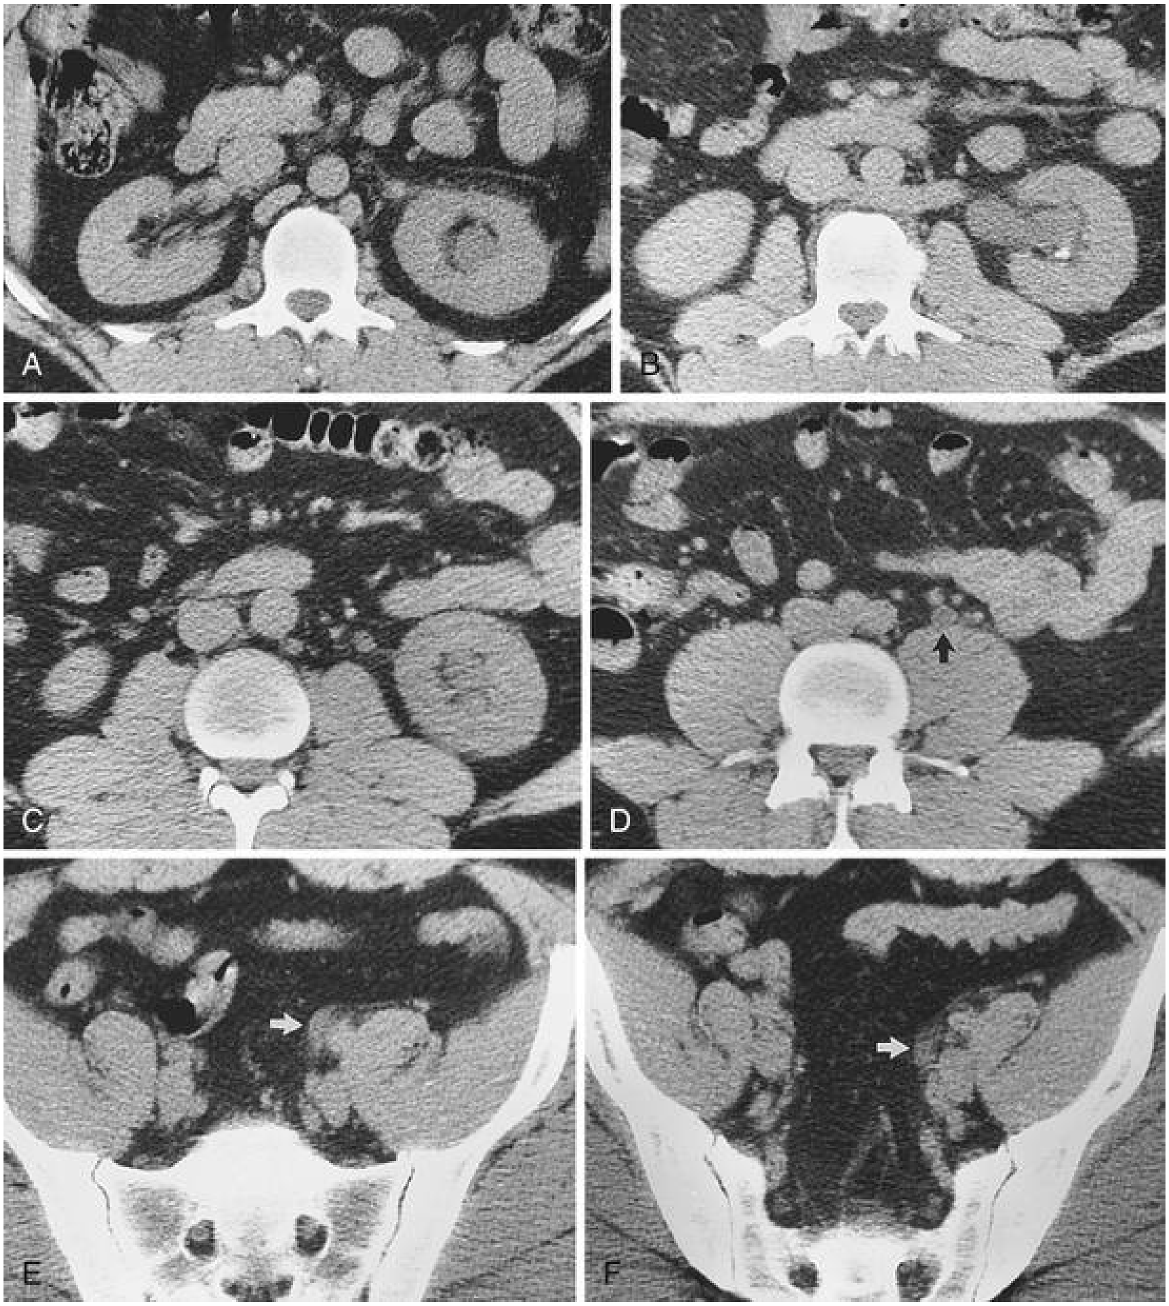
(solid arrows) near the ureterovesical junction. The bladder *(b)* is filled with urine and partially opacified with contrast material. The normal seminal vesicle *(open arrows)* usually has a paired bow-tie structure with slightly lobulated contour. *a,* Right external iliac artery; *r,* rectum; *v,* right external iliac vein. (J) Scan at the level of the pubic symphysis *(open arrow)* reveals the prostate gland *(solid arrow). a,* Right external iliac artery; *m,* obturator internus muscle; *r,* rectum; *v,* right external iliac vein.

Hounsfield Units

A single CT image generated by the scanner is divided into many tiny blocks of different shades of black and white called pixels. The actual gray scale of each pixel on a CT depends upon the amount of radiation absorbed at that point, which is termed an *attenuation value*. **Attenuation values are expressed in Hounsfield units (HU). The Hounsfield units scale or attenuation value is based upon a reference scale in which air is assigned a value of −1000 HU and dense bone is assigned the value of +1000 HU. Water is assigned 0 HU.**

Urolithiasis

Patients in the emergency department with abdominal pain or renal colic are frequently evaluated with CT imaging. The use of nonenhanced CT imaging to identify urolithiasis was first reported in 1995 (Smith et al., 1995) and has become the standard diagnostic tool to evaluate renal colic. It offers the advantage over IVU of avoiding contrast and has the ability to diagnose other abdominal abnormalities that can also cause abdominal pain. MDCT can readily diagnose radiolucent stones that may not have been seen on IVU, as well as small stones even in the distal ureter (Federle et al., 1981). **With the exception of some indinavir stones, all renal and ureteral stones can be detected on helical CT scan** (Schwartz et al., 1999). In the workup of urolithiasis, the unenhanced CT has a sensitivity ranging between 96% and 100% and specificity ranging between 92% and 100% (Memarsadeghi et al., 2005). **Stones in the distal ureter can be difficult to differentiate between pelvic calcifications. In these cases, the urologist needs to look for other signs of obstruction that indicate the presence of a stone, including ureteral dilation, inflammatory changes in the perinephric fat, hydronephrosis, and a soft-tissue rim surrounding the calcification within the ureter. The soft-tissue rim around a stone represents irritation and edema in the ureteral wall** (Dalrymple et al., 2000; Heneghan et al., 1997) (Fig. 3.18).



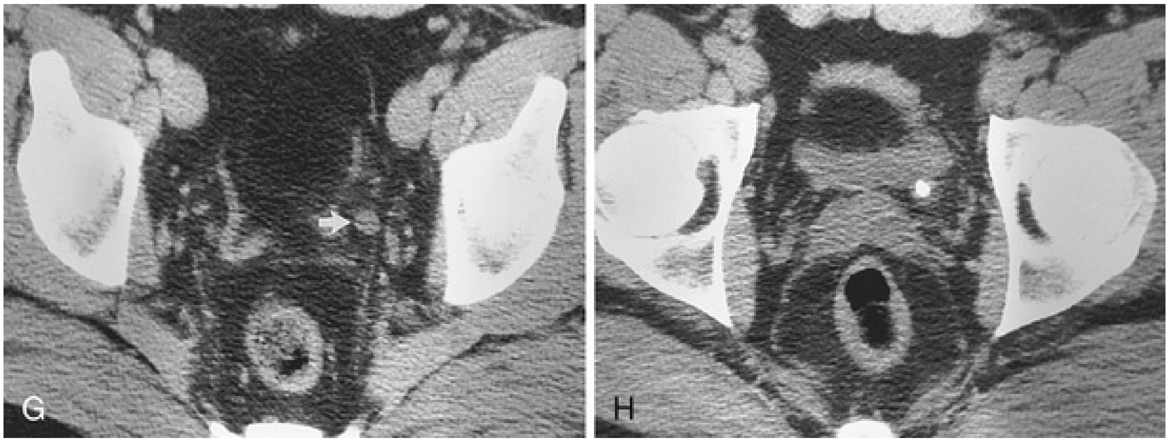


FIG. 3.18 CT of the abdomen and pelvis in patient with an obstructing ureteral stone at the level of the ureterovesicle junction. (A) Level of the left upper pole. Mild renal enlargement, caliectasis, and perinephric stranding are apparent. (B) Level of the left renal hilum. Left pyelectasis with a dependent stone, mild peripelvic and perinephric stranding, and a retroaortic left renal vein are shown. (C) Level of the left lower pole. Left caliectasis, proximal ureterectasis, and mild periureteral stranding are present. (D) Level of the aortic bifurcation. The dilated left ureter *(arrow)* has lower attenuation than do nearby vessels. (E) Level of the upper portion of the sacrum. A dilated left ureter *(arrow)* crosses anteromedial to the common iliac artery. (F) Level of the midsacrum. A dilated left ureter *(arrow)* is accompanied by periureteral stranding. (G) Level of the top of the acetabulum showing a dilated pelvic portion of the left ureter *(arrow).* (H) Level of the ureterovesical junction. The impacted stone with a “cuff” or “tissue rim” sign that represents the edematous wall of the ureter. (Reprinted from Talner LB, O'Reilly PH, Wasserman NF: Specific causes of obstruction. In Pollack HM, et al., eds: *Clinical urography,* ed 2, Philadelphia, 2000, Saunders.)

Stone patients are frequently subjected to radiation exposure as part of diagnosis, treatment, and follow-up. Increasing awareness of the potential long-term adverse effects of radiation exposure has encouraged urologists and radiologists to discover means to decrease the amount of radiation exposure. The low-dose unenhanced helical CT scan is gaining increasing popularity for initial diagnosis of renal colic suspected to be due to urolithiasis and for follow-up in stone patients. Using low-dose CT protocols, the specificity and sensitivity of unenhanced low-dose helical CT scan are approximately 96% and 97%, respectively. Low-dose techniques offer a 99% positive and 90% negative predictive value for urolithiasis. The end result is a 50% to 75% decrease in the patient's total radiation exposure for each CT obtained (Hamm et al., 2002; Kalra et al., 2005; Liu et al., 2000).

Cystic and Solid Renal Masses

The frequent CT imaging in emergency room patients has resulted in an increase in the detection of incidental renal masses. With use of CT imaging, the mass can be characterized as a simple or complex cyst or a solid mass. Based upon the Hounsfield unit attenuation scale, we would expect simple cysts to have Hounsfield units near zero (Fig. 3.19).

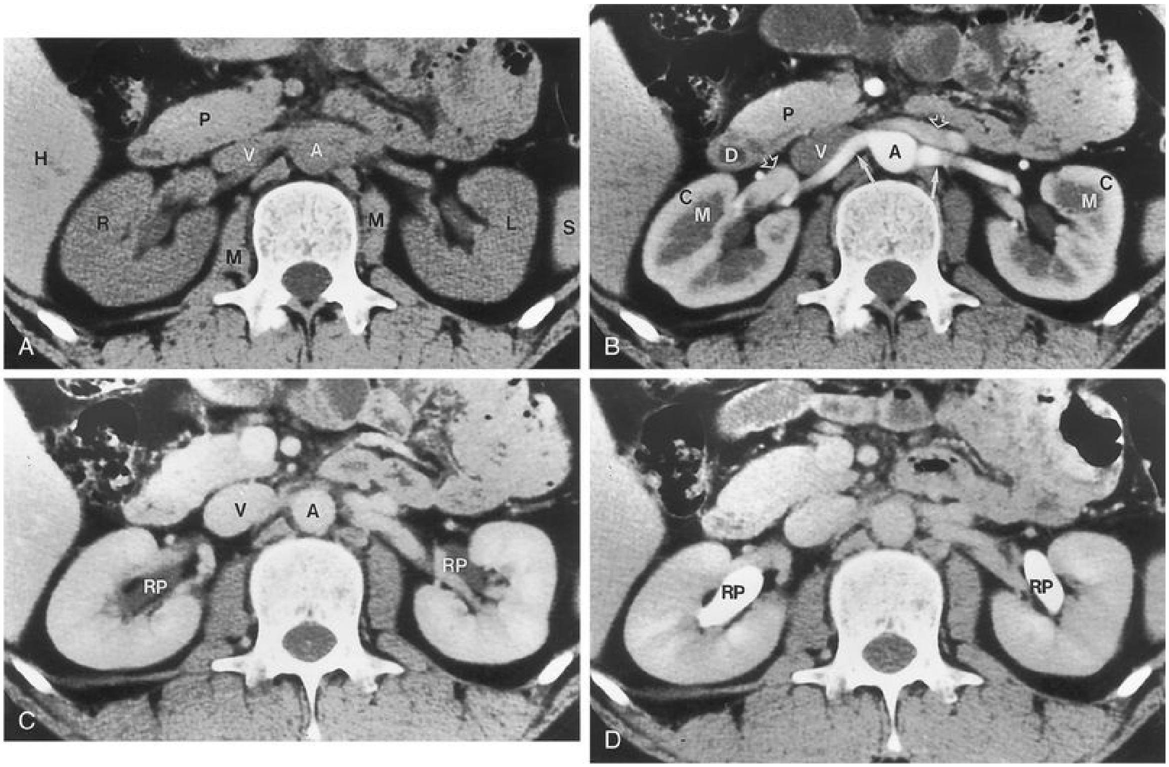

FIG. 3.19 **Renal CT demonstrating normal nephrogenic progression.** (A) Unenhanced CT scan obtained at the level of the renal hilum shows right *(R)* and left *(L)* kidneys of CT attenuation values slightly less than those of the liver *(H)* and pancreas *(P). A,* Abdominal aorta; *M,* psoas muscle; *S,* spleen; *V,* inferior vena cava. (B) Enhanced CT scan obtained during a cortical nephrographic phase, generally 25 to 80 seconds after contrast medium injection, reveals increased enhancement of the renal cortex *(C)* relative to the medulla *(M).* The main renal artery is indicated with *solid arrows* bilaterally. Main renal veins *(open arrows)* are less opacified with respect to the aorta *(A)* and arteries. *D,* Duodenum; *P,* pancreas; *V,* inferior vena cava. (C) CT scan obtained during the homogeneous nephrographic phase, generally between 85 and 120 seconds after contrast medium administration, reveals a homogeneous, uniform, increased attenuation of the renal parenchyma. The wall of the normal renal pelvis *(RP)* is paper thin or not visible on the CT scan. *A,* Abdominal aorta; *V,* inferior vena cava. (D) CT scan obtained during the

excretory phase shows contrast medium in the RP bilaterally; this starts to appear approximately 3 minutes after contrast medium administration.

When the unenhanced CT images of a renal mass are compared with the enhanced images obtained in the cortical medullary or nephrogenic phase, an increase in Hounsfield units (measured in the area of the renal mass) by 15 to 20 HU confirms the presence of a solid enhancing mass, which is usually renal cancer. Pseudoenhancement is maximal when small (≤1.5-cm) intrarenal cysts are scanned during maximal levels of renal parenchymal enhancement. The magnitude of this effect varies with scanner type but may be large enough to prevent accurate lesion characterization, despite use of a thin-section helical CT data acquisition technique (Birnbaum et al., 2002). **The presence of fat, which should enhance less than 10 HU, is diagnostic for angiomyolipoma. A hyperdense cyst shows no change in density between the postcontrast and delayed phase images.**

Complex cystic masses are usually characterized based upon the Bosniak classification system. The most important criterion used to differentiate a lesion that should be considered for surgery versus a nonsurgical lesion is the presence or absence of tissue vascularity or enhancement. Bosniak category I, II, and IIF lesions do not enhance to any measurable degree. Category I lesions are simple cysts and considered to be benign. Category II lesions are more complicated and may have calcifications, high attenuation fluid, and several thin septae. Category III lesions are more complex, have small areas of calcification, and may also have irregular walls or septate where there is measurable enhancement. Cystic lesions discovered on CT scan that are difficult to categorize as either II or III are now currently categorized as IIF. **Bosniak III lesions have been reported to be malignant renal cell carcinoma in 60% of cases and require close follow-up or surgical extirpation. Bosniak category IV lesions are cystic masses that meet all the criteria of category III but also have enhancing soft-tissue components adjacent or independent of the wall or septum of the cyst and have been reported to be malignant RCC in 100% of cases** (Bosniak, 1997; Curry, 2000; Israel and Bosniak, 2005).

Hematuria

The CTU is one of the most common studies ordered for the workup of gross or microscopic hematuria. With MDCT it is possible to perform a comprehensive evaluation of the patient with a single examination (Chai et al., 2001). The study images the abdomen and pelvis and typically includes four different phases. The first scan is an unenhanced CT to distinguish between different masses that can be present in the kidney and uncover kidney stones that would later be obscured by the excretion of contrast into the renal collecting system. At 30 to 70 seconds after contrast injection, the corticomedullary phase is captured with another pass through the MDCT, helping to define vasculature and perfusion. The nephrogenic phase occurs between 90 to 180 seconds after injection of contrast and, when compared with the nonenhanced images, allows sensitive detection and characterization of renal masses. The final phase is the excretory phase, imaged approximately 3 to 5 minutes after injection of contrast. The excretory phase allows complete filling of the collecting system and usually allows visualization of the ureter (Joudi et al., 2006).

CTU has been shown to be sensitive in detecting upper tract urothelial cancers. In one series of 57 patients with hematuria, 38 were found to have urothelial carcinoma. CT urography detected 37/38 urothelial cancers for a sensitivity of 97%, compared with retrograde pyelogram, which detected 31/38 lesions and had a sensitivity of 82%. Approximately 90% of malignant upper tract lesions can be detected with CT urography (Caoili et al, 2005; Lang et al., 2003; McCarthy and Cowan, 2002). CT urography is not as sensitive as cystoscopy for the detection of urothelial tumors in the bladder. Only large bladder tumors are visualized with CT imaging studies as filling defect in the lumen of the bladder. Carcinoma in situ cannot be visualized on CT scanning and therefore cystoscopy is still an important part of a comprehensive hematuria workup.

Key Points: Computed Tomographic Imaging

- The CTU is an excellent imaging choice to evaluate the kidney, upper tract collecting system, and ureter.
- The CTU is highly sensitive and specific for upper tract urothelial carcinoma.
- A renal mass in the kidney seen on CTU that enhances more than 15 to 20 HU is most likely a renal cancer.
- With the exception of indinavir stones, all urolithiasis is visible on unenhanced CT of the abdomen and pelvis.

Magnetic Resonance Imaging

CT imaging remains the mainstay of urologic cross-sectional imaging. Continued technologic improvements in MRI is narrowing the overall resolution quality gap between these two techniques. A significant advantage of MRI is the excellent signal contrast resolution of soft tissue without the need for intravenous contrast in many situations.

To obtain MRIs, the patient is placed on a gantry that passes through the bore of a magnet. When exposed to a magnet field of sufficient strength, the free water protons in the patient orient themselves along the magnetic field's z-axis. This is the head-to-toe axis, straight through the bore of the magnet. A radiofrequency (RF) antenna or “coil” is placed over the area of interest. It is the coil that transmits the RF pulses through the patient. When the RF pulse stops, protons release their energy, which is detected and processed to obtain an MRI. An MR sequence exploits the body's different tissue characteristics and the manner that each type of tissue absorbs and then releases this energy. Currently, most coils can transmit and receive signal, which is referred to as dual-channel RF.

Weighting of the image depends on how the energy is imparted through the physics of the pulse sequence and whether the energy is released quickly or slowly. Images are described as T1 or T2 weighted. The T1-weighted images are generated by the time to return to equilibrium in the z-axis. The T2-weighted images are generated by the time required to return to equilibrium in the xy-axis. **On T1-weighted MRIs, fluid has a low signal intensity and appears dark. T2-weighted MRIs have a high signal intensity and appear bright. In the kidney this translates into the cortex having a higher signal intensity or being brighter than the medulla, which gives off a lower signal and is darker.**

MRI has significant advantages over other imaging modalities. First, and most importantly, there are no risks associated with secondary malignancies from radiation exposure (Berrington de González and Darby, 2004). It is the modality of choice in patients who are pregnant, suffer from renal insufficiency, and/or have an iodine contrast allergy.

The contrast agents in MRI are noniodinated compounds. Iodinated compounds as used in CT imaging function by absorbing x-rays. **GBCAs shorten the relaxation times of water** (Lin and Brown, 2007). This results in an increase in signal intensity (enhancement), most commonly assessed in a T1 sequence. Gadolinium is a toxic heavy metal that is chelated to prevent cellular absorption and any associated toxicities (Lin and Brown, 2007). The dose of gadolinium is nontoxic for almost all patients, except ones with *severe* renal insufficiency.

Nephrogenic systemic fibrosis (NSF) occurs in patients with acute or chronic renal insufficiency with a GFR less than 30 mL/min/1.73 m^2 and was first described in 2000 (Cowper et al., 2000). Gadolinium is deposited in skin and muscle as an insoluble precipitate, which leads to the systemic fibrosis (Grobner, 2006). In response, the FDA has issued warnings regarding the association between NSF and GBCAs because there is no effective treatment available (US Food and Drug Safety Communication, 2010). The current guidelines are available at the FDA.gov official website and the US Food and Drug Administration website. In addition, there have been documented cases of gadolinium deposition (linear > macrocyclic) within deep brain tissue. However, the clinical significance of deposition is unknown, and no adverse events have been documented. Current recommendations include favoring the use of macrocyclic agents over linear GBCAs well as a continued analysis of possible future risks associated with GBCAs as the data continue to evolve (Gulani et al., 2017).

Adrenal Magnetic Resonance Imaging

One of the key differences between MRI and other imaging modalities is the ability of MRI to characterize soft tissues without the use of intravenous contrast. In the adrenal gland minute quantities of lipids can help differentiate between malignancies and benign adenomas. Most adrenal masses are identified incidentally and are nonfunctioning.

Adrenal adenomas are usually less than 3 cm and nonfunctional (Boland and Blake, 2008). Adrenal adenomas have a high lipid content (74%), which makes them more readily differentiated from malignant processes (Dunnick and Korobkin, 2002).

Inversion-recovery imaging, chemical shift imaging (CSI), and fat saturation imaging are three approaches to assess lipid content on masses. These approaches use the differences in the behavior of fat protons and water protons within the magnetic field. CSI is the most commonly used technique for urologic patients. Spectral presaturation with inversion recovery (SPIR) and spectral presaturation attenuated inversion recovery (SPAIR) can also be used to detect fat via selective excitation of the fat protons and T1 relation techniques (Ünal et al., 2016).

Adrenal Adenoma

Adrenal adenomas are characterized by assessing the lipid content within the cells. CSI uses the difference in the behavior of water protons (H_2O) versus fat protons ($-CH_2-$). The oxygen atom in water pulls on the electron cloud surrounding the hydrogen atom, whereas the carbon atom in fat is less electronegative and has a decreased effect on the hydrogen electron cloud (Pokharel and Macura, 2013). This difference in the magnetic field (shielding) for these two types of protons is the precession frequencies or the CSI (Pokharel and Macura, 2013).

CSI obtains images “in-phase” (IP) and “out-of-phase” (OP) regarding the water and fat protons. The signals detected for a given voxel can be additive or canceled out. The IP imaging refers to the contribution of fat and water, or additive, to the signal at a given voxel. This occurs when the echo time (TE) is set to align the fat and water protons.

In the OP imaging the TE is set to cancel the signals obtained, thus the subtraction of the protons results in a decrease, or canceling, in signal at that given voxel and produces a lower signal intensity if fat and water are present.

The next step is to compare the two data sets (IP and OP) obtained to determine if there is a loss of signal (decrease) on the OP images, which is indicative of intracytoplasmic fat (Fig. 3.21). If there is no change between the two data sets, then there is a lower probability that fat is present within the mass. This was initially determined on a qualitative basis by visually comparing signal intensities between the two sequences (Korobkin and Giordano, 1996). The loss of signal on CSI MRI is 92% sensitive and has a limited specificity of 17% for adrenal adenoma (Boland and Blake, 2008).

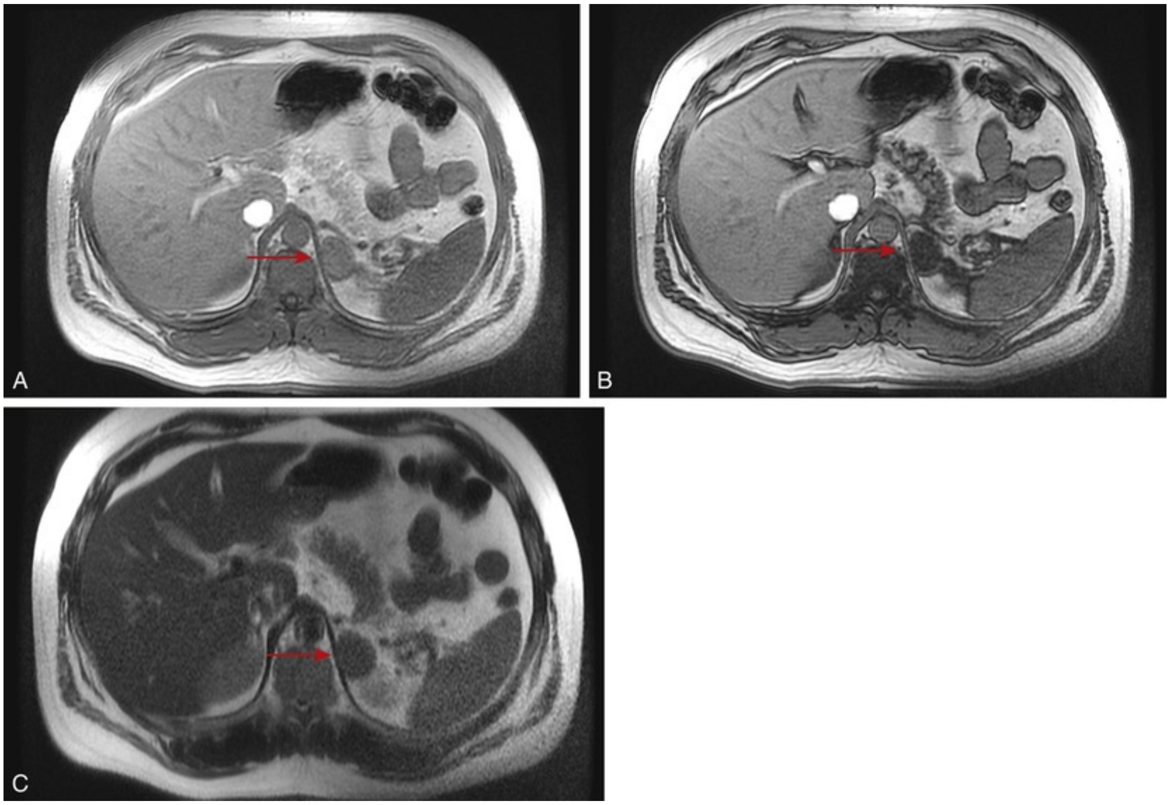

FIG. 3.21 A 45-year-old man underwent a 1.5T MRI with chemical shift imaging, which was consistent with left adrenal adenoma *(red arrow).* (A) In-phase (IP) T1-weighted image demonstrates a left adrenal mass with signal isointense to muscle. (B) Out-of-phase T1-weighted imaging shows drop out of signal in a left adrenal mass relative to the IP imaging. (C) Single-shot T2-weighted spin echo image reveals a left adrenal nodule with low signal intensity.

Other authors have attempted to determine signal intensity (SI) index by quantitatively comparing the IP and OP images. Nakamura and Namimoto (2012) reported that using a 5% SI yielded an accuracy of 100% (3 Tesla) in determining if intracytoplasmic lipid was present and thus a diagnosis of an adenoma. Although there are currently no set thresholds, cutoff ranges are reported to be between 1.7% and 20% (Nakamura and Namimoto, 2012). The limited specificity reported by the qualitative approach (17%) was increased to 100% specificity using the quantitative SI index (Nakamura and Namimoto, 2012).

$$\text{Signal intensity (SI) index (\%)} = (\text{SI in-phase} - \text{SI out-of-phase}) / \text{SI in-phase} \times 100$$

In some clinical situations, lipid-poor adenomas (10%–30% incidence) can result in an indeterminate study (Elsayes and Mukundan, 2004). The typical washout of an adrenal cortical carcinoma is slow. Therefore an enhanced CT with washout may be a better study to differentiate lipid-poor adrenal adenomas from other adrenal masses (Park and Kim, 2007). In cases of unilateral adenomas data suggest there are limitations associated with localization using CT/MRI and adrenal vein sampling may be a useful adjunct to the diagnostic pathway (Ladurner et al., 2017).

Adrenal Cortical Carcinoma

An adrenal cortical carcinoma (ACC) diagnosis is obtained using a combination of clinical factors and imaging characteristics (Fig. 3.20). In a review by Ng and Libertino, ACC is hormonally active in 62% of cases (Ng and Libertino, 2003). **The incidence of ACC is related to size and adrenal lesions equal to or less than 4 cm represented 2% of all ACC diagnosed. The incidence of ACC increased to 6% for lesions 4 to 6 cm and to 25% for lesions greater than 6 cm** (Mansmann and Lau, 2004). T2-weighted and T1-weighted images with Gd are usually heterogeneous with a high signal intensity and a heterogeneous enhancement, respectively. CSI exhibits a low signal (Bharwani and Rockall, 2011). **ACC also is associated with local vascular thrombosis, which can be detected on MRI** (Mezhir and Song, 2008). ACC has an increased metabolic activity and can be visualized on FDG-PET imaging, and this can differentiate ACC from adenomas with 100% sensitivity and 88% specificity (Groussin and Bonardel, 2009).

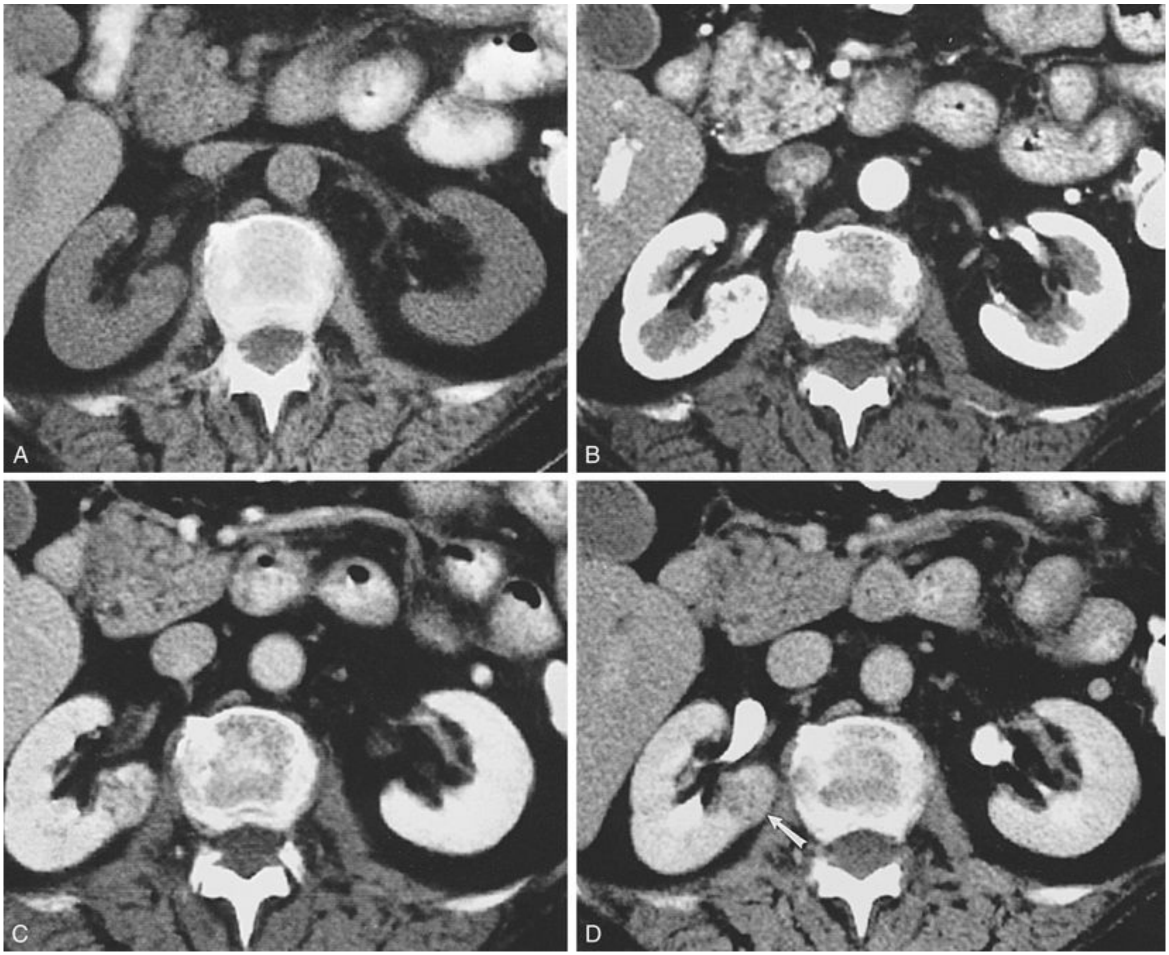

FIG. 3.20 Small renal cell carcinoma in the infrahilar lip of the right kidney is not easily seen on unenhanced image (A). On corticomedullary phase image (B), the lesion is subtly visible as a hyperenhancing focus within the renal medulla. On nephrographic (C) and pyelographic phase (D) images, the full extent of the lesion *(arrow)* within the medulla and cortex is depicted. (Reprinted from Brink JA, Siegel CL: Computed tomography of the upper urinary tract. In Pollack HM, et al., eds: *Clinical urography,* ed 2, Philadelphia, 2000, Saunders.)

Myelolipoma

Myelolipoma is a benign adrenal mass that consists of mature fatty tissues and bone marrow elements. Myelolipoma occurs in approximately 6.5% of patients with incidentally detected adrenal masses (Song and Chaudhry, 2008). The complicating issues with myelolipomas is that the size of the mass can be greater than 4 cm, and this carries significant overlap with malignant adrenal lesions (Meyer and Behrend, 2005). On MRI a myelolipoma has a high signal intensity on T1-weighted imaging, suppressed signal on frequency selective fat suppression, and an India ink artifact (Figs. 3.22 and 3.23) (Taffel and Haji-Momenian, 2012). India ink artifact appears as a dark line around the lesion and/or organs and is the result of a voxel containing fat and water on CSI OP images.

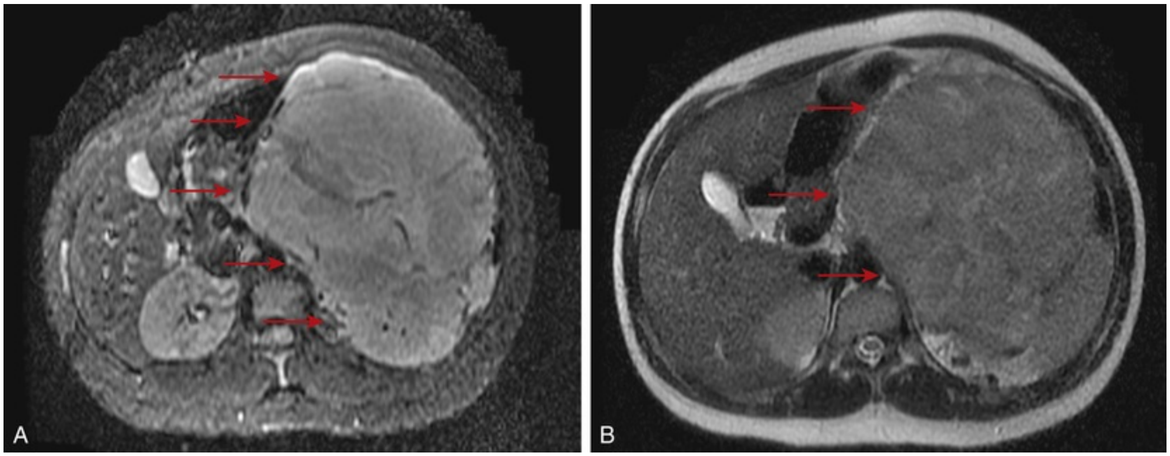

FIG. 3.22 A 65-year-old woman with left side heterogeneous enhancing suprarenal lesion (ACC) with select images from a 1.5T abdominal MRI. (A) Moderately weighted T2 STIR images with a hyperintense signal *(red arrow).* (B) Heavily weighted T2 single shot fast spin echo isointense signal. These findings are all dependent on the degree of T2 weighting.

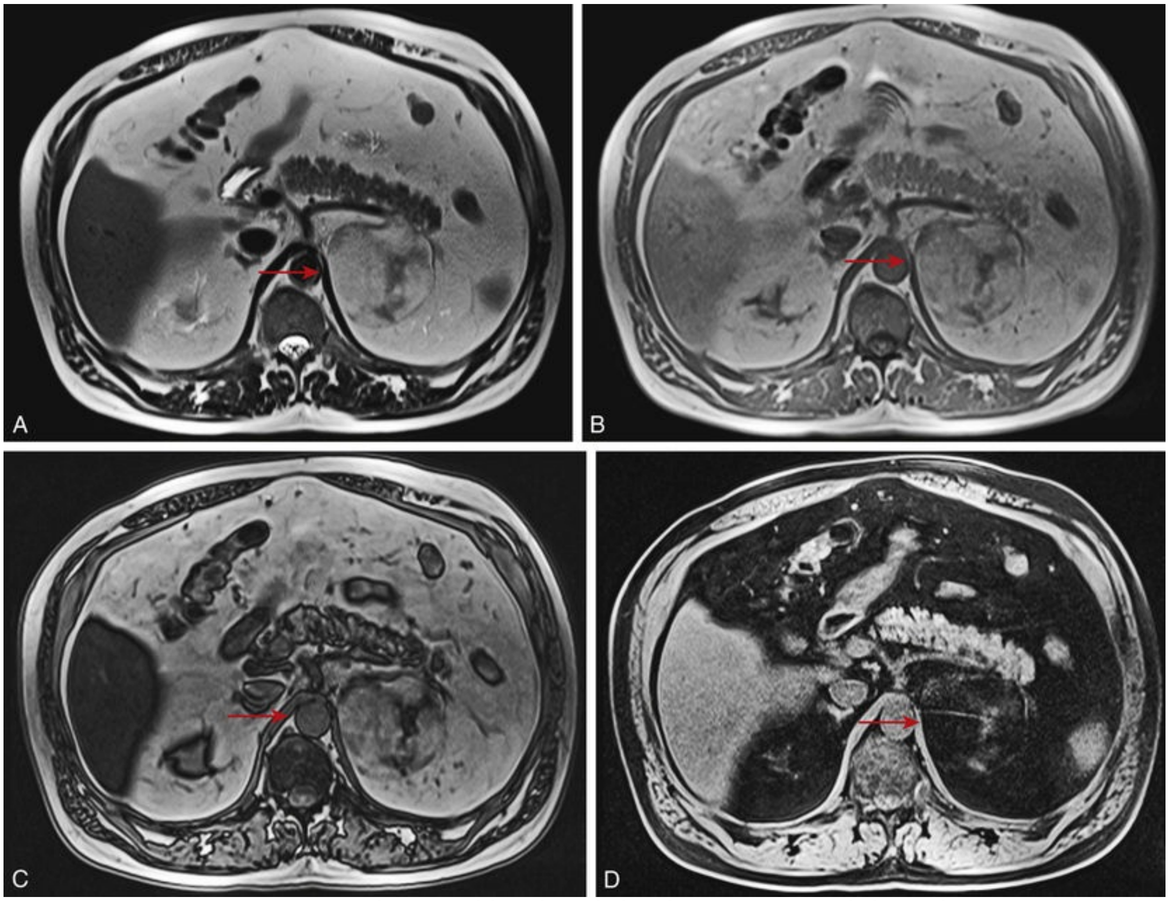

FIG. 3.23 A 44-year-old man with prior abdominal ultrasound detecting an indeterminate renal mass underwent a 1.5T MRI with chemical shift imaging, which was consistent with left adrenal myelolipoma *(red arrow).* (A) T2 single-shot spin echo demonstrates a large left adrenal mass with signal isointense to abdominal fat. (B) T1 in-phase (IP) imaging demonstrates a left adrenal mass, which signals similar to the abdominal fat. (C) T1 out-of-phase imaging shows no drop of signal compared with IP imaging. (D) T1 fat-suppressed precontrast imaging shows loss of signal within the mass consistent with gross fat.

Metastasis

An adrenal mass is considered to be metastatic in the setting of a known primary malignancy. The MRI findings are consistent with a large, irregular, heterogeneous mass with occasional necrosis present on imaging. Metastasis have a high signal on T2-weighted images secondary to higher fluid content compared with adrenal adenoma (Shadev, 2010). Gadolinium enhancement on T1-weighted images demonstrates heterogeneous enhancement with a delayed peak enhancement (65 seconds) when compared with adrenal adenomas (40 seconds) (Inan and Arslan, 2008). Using a time to peak enhancement cutoff of

53 seconds or greater resulted in 87.5% sensitivity and 80% specificity in characterizing metastatic adrenal lesions (Inan and Arslan, 2008).

Patients with primary lesions known to contain intracytoplasmic fat may require additional imaging to better differentiate an adrenal gland lesion. The metastatic sites often carry the same histologic features as the primary tumor. This can result in a false positive for adrenal adenomas if the primary contains intracytoplasmic lipids content (chemical shift MRI positive) (Fig. 3.24) (Krebs and Wagner, 1998). This has been reported in liposarcoma, renal cell carcinoma, and hepatocellular carcinoma (Krebs and Wagner, 1998; Sydow and Rosen, 2006).

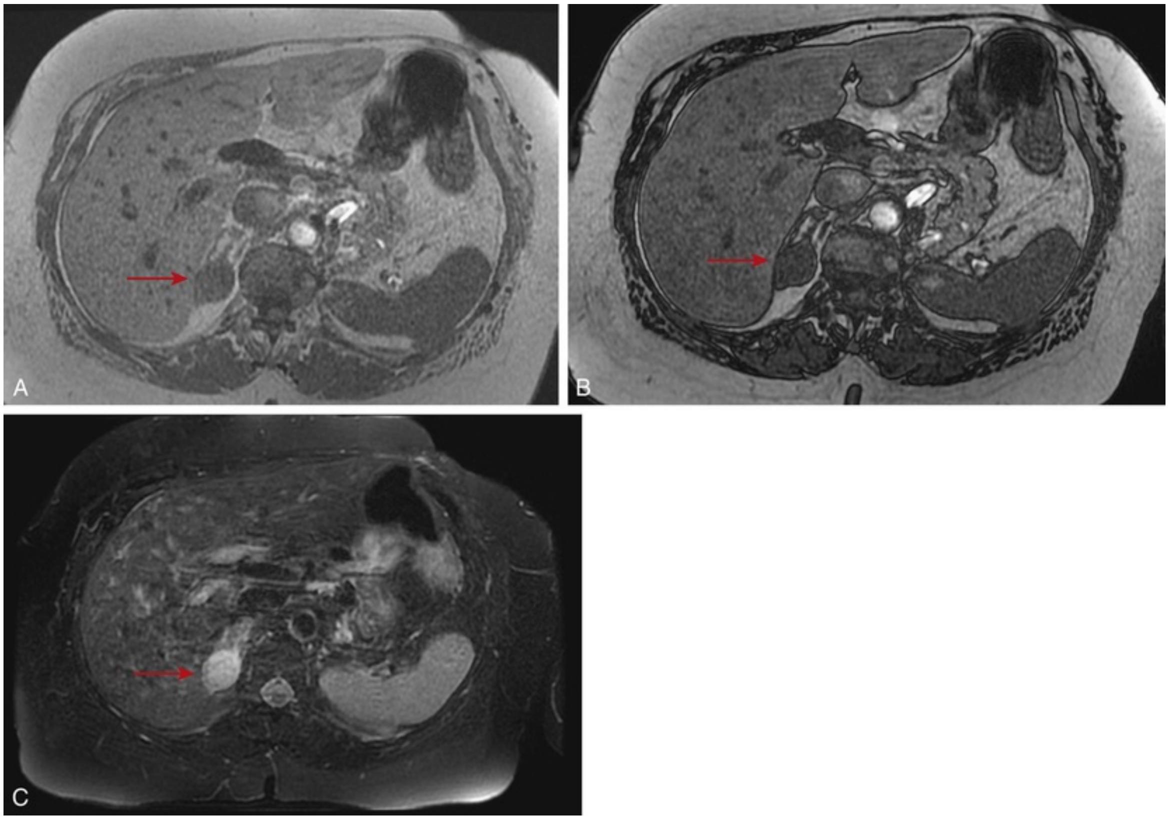

FIG. 3.24 A 63-year-old female s/p right nephrectomy for clear cell carcinoma with a metachronous right adrenal metastasis. (A) T1 in-phase imaging of the right adrenal mass *(red arrow).* (B) T1 out-of-phase imaging with drop in signal *(red arrow)* consistent with microscopic fat. (C) Fat-suppressed fast relaxation fast spin echo moderately weighted T2 image with hyperintense signal *(red arrow).*

Pheochromocytoma

Pheochromocytoma traditionally was considered to be diagnostic if on T2-weighted images the lesion demonstrated an increased signal intensity (Fig. 3.25). However, Varghese and Hahn reported that 35% of pheochromocytomas demonstrated low T2 signal contrary to conventional teaching (Varghese and Hahn, 1997). **Pheochromocytoma, adrenal cortical carcinoma, and metastatic lesions to the adrenal gland can exhibit a hyperintense signal intensity or "bright" on T2-weighted images.** It is important to understand that the signal intensity can vary because of the degree of weighting of the T2 signal and would not exhibit the traditional findings of "being bright" on T2-weighted images (see Figs. 3.21 to 3.23). The pheochromocytoma may be characterized by MRI without the need for contrast enhancement.

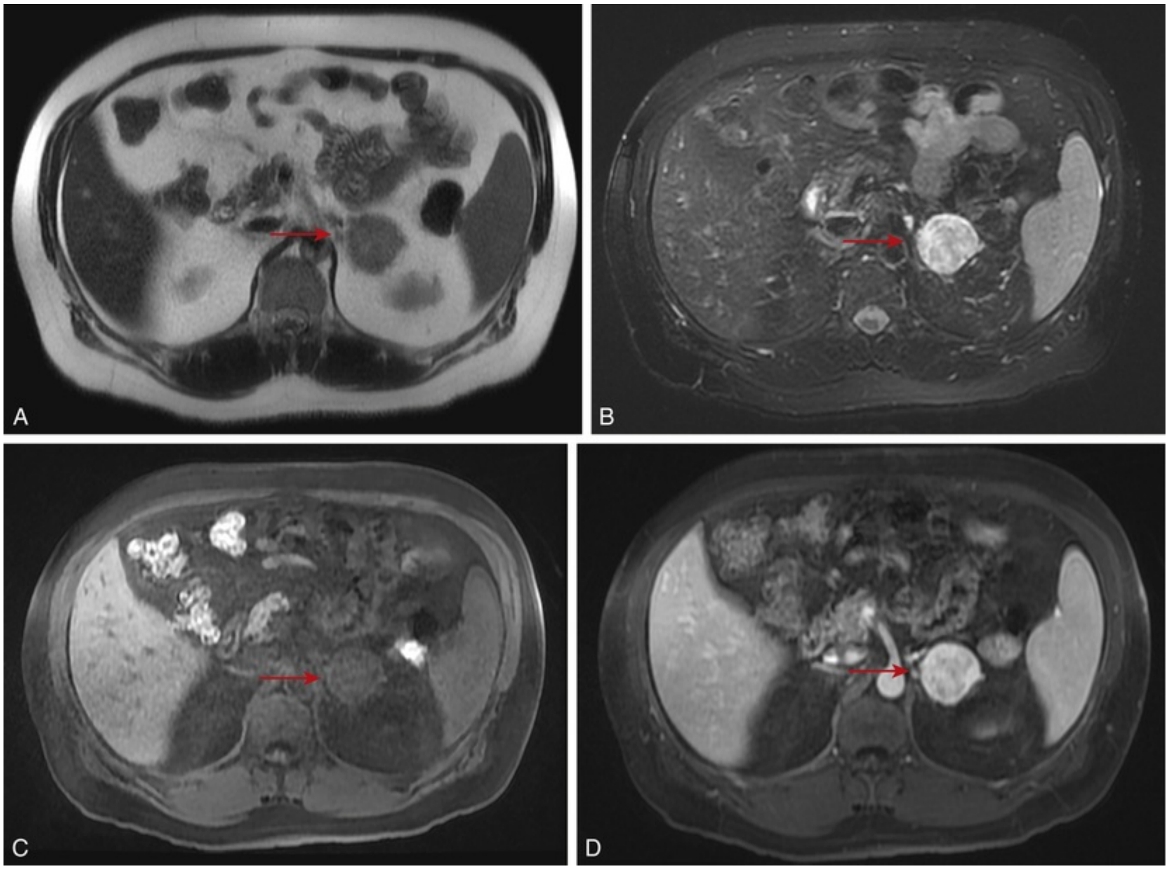

FIG. 3.25 A 50-year-old man with a left side pheochromocytoma and select images from a 1.5T MRI. (A) Heavily weighted T2 single-shot fast spin echo with an isointense signal (not bright). (B) Moderately weighted T2 fat-suppressed fast recovery fast spin echo with hyperintense signal (bright). (C) T1-weighted precontrast images. (D) T1-weighted postcontrast images with marked early enhancement.

Other Adrenal Lesions

Lymphoma, neuroblastoma, ganglioneuroma, hemangioma, and granulomatous diseases of the adrenal gland have an intermediate SI index on chemical shift MRI and other imaging findings (Table 3.5).

TABLE 3.5

Morphologic and Imaging Characteristics of Incidental Adrenal Lesions

IAL	SIZE (cm)	SHAPE	TEXTURE	UNENHANCED CT ATTENUATION (HU)	15-MINUTE CT WASHOUT (%)
Adrenal metastasis	Variable	Variable	Heterogeneous when larger	>10	RPW < 40
Adrenal cortical carcinoma	> 4 cm	Variable	Variable	>10	RPW < 40
Pheochromocytoma	Variable	Variable	Variable	>10 rarely <10	RPW < 40
Cyst	Variable	smooth, Round	Smooth	<10	does not enhance
Adenoma	1–4 cm	Smooth, round	Homogeneous	<10 in 70%	RPW > 40; APW > 60
Myelolipoma	1–5 cm	Smooth, round	Variable with macroscopic fat	<0, often <-50	No data
Lymphoma	Variable	Variable	Variable	>10	RPW < 40
Hematoma	Variable	Smooth	Variable	>10, sometimes >50	No data
Neuroblastoma	Variable	Variable	smooth, Round	>10	RPW < 40
Ganglioneuroma	Variable	Variable	Variable	>10	No data
Hemangioma	Variable	Variable	Variable	>10	No data
Granulomatous	1–5 cm	Smooth	Usually Homogeneous	>10	No data

APW, Absolute percentage washout; *MIBG,* m-iodobenzylguanidine; *OP,* out-of-phase; *RPW,* relative percentage washout; *SI,* signal intensity.

Data from Boland and Blake, 2008 and Taffel and Haji-Momenian, 2012.

Adrenal hematomas have variable imaging characteristics on MRI because of changes in the hematoma from initial acute bleeding to breakdown products of red blood cells with deposition of hemosiderin within the hematoma. This progresses from an iso-intense to hypointense signal on T1 and low signal on T2 to hyperintense on T1 fat-suppressed sequences and T2 sequences at 1 to 7 weeks. A low signal rim is present on T1 and T2 sequences because of hemosiderin deposits (Taffel and Haji-Momenian, 2012).

Renal Magnetic Resonance Imaging

Simple cysts have similar characteristics on ultrasound, CT, and MRI. Complex cysts can be differentiated or characterized using MRI. Hemorrhage within a cyst results in a high signal on T1-weighted images because of the paramagnetic effects of the byproducts from the breakdown of blood (hemosiderin) (Fig. 3.26) (Roubidoux, 1994).

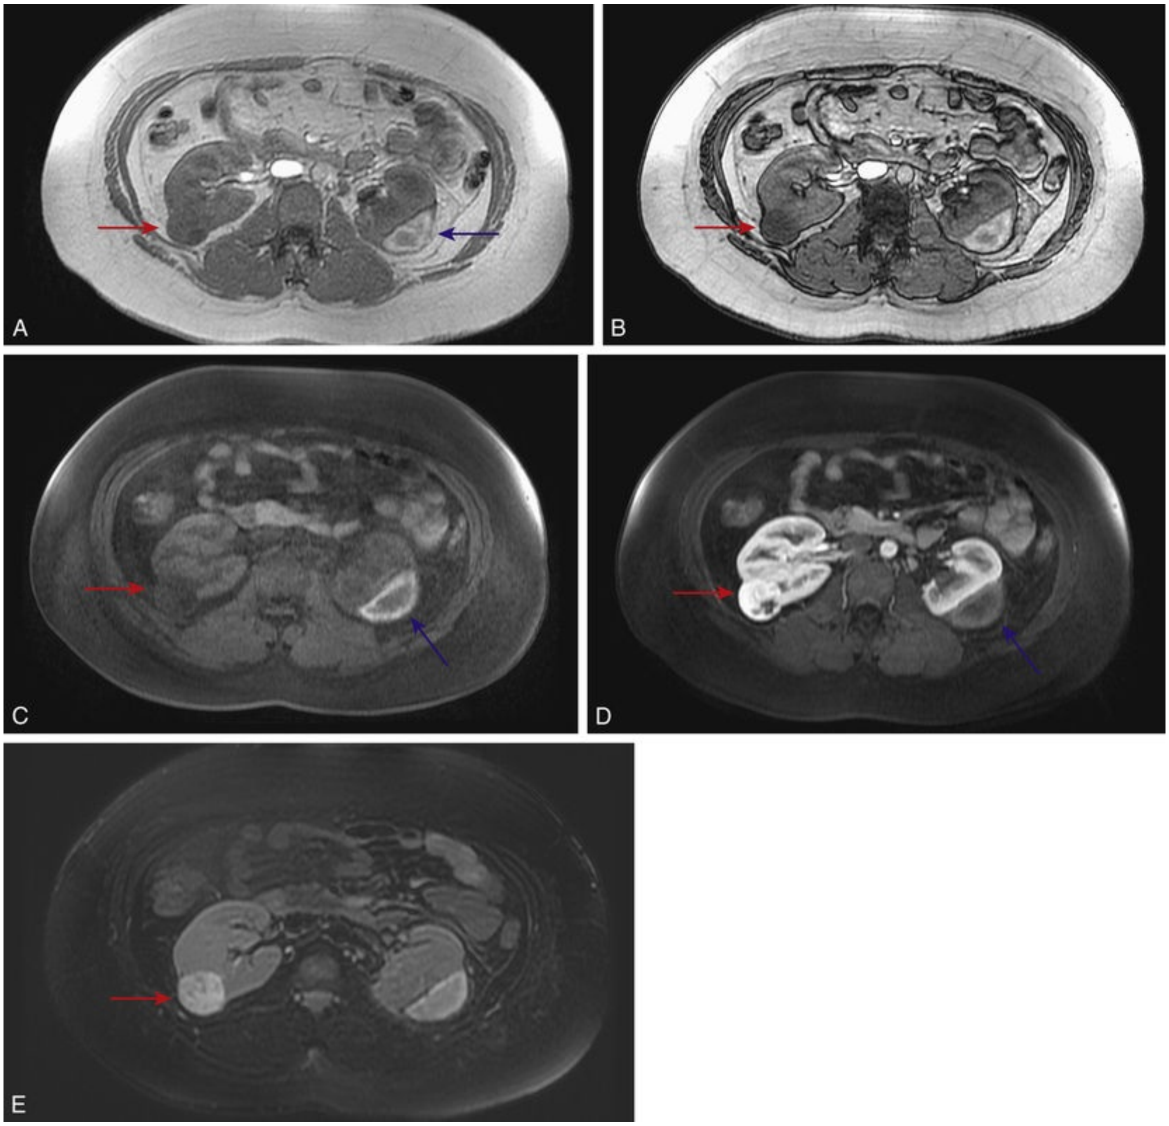

FIG. 3.26 A 31-year-old woman after left extracorporeal shock wave lithotripsy with a subcapsular hematoma and right-side pathology confirmed 3.5-cm clear cell carcinoma underwent a 1.5T MRI of the abdomen. (A) T1-weighted in-phase (IP) imaging of a right renal nodule with mild heterogeneity *(red arrow)* but primarily isointense signal intensity. Left kidney subcapsular hematoma with a rim of high signal intensity *(blue arrow).* (B) T1-weighted out-of-phase (OP) image shows diffuse signal dropout within the renal nodule consistent with microscopic fat. (C) T1-weighted fat-suppressed precontrast image with a low signal intensity of the right renal nodule *(red arrow)* and high signal intensity of the left subcapsular hematoma *(blue arrow)*. Blood is high signal intensity on precontrast T1-weighted images. (D) T1 fat-suppressed postcontrast images of the right renal nodule with avid heterogeneous enhancement. Nonenhancing left subcapsular hematoma. (E) Diffusion-weighted imaging b-1000 demonstrates high signal intensity throughout the right renal nodule.

Proteinaceous contents within a cyst demonstrate high signal on T1-weighted images. Chronic hemorrhage results in a black ring along the cyst wall on T2-weighted images. **For benign and complex cysts there should be no enhancement** (Israel and Hindman, 2004).

When independent risk factors were evaluated for RCC, enhancement of the cyst wall had higher sensitivity and specificity than calcifications on the cyst wall. Calcifications can cause artifacts that may decrease the ability to appreciate enhancement of small nodules within the wall of a complex cyst on CT imaging. MRI has the advantage of not being influenced by calcifications within the wall of a complex cyst. Calcifications appear as a void on MRI. Therefore MRI is more likely to detect enhancement of a renal cell carcinoma in the wall of a complex cyst compared with CT imaging when mural calcifications are present (Israel and Bosniak, 2003).

MRI offers a distinct advantage over CT imaging in the evaluation of the pseudocapsule, which appears on T1- and T2-weighted images as a low signal surrounding the lesion. The lack of pseudocapsule surrounding a renal mass had an accuracy of 91% in predicting pT3a disease (Roy and El Ghali, 2005).

MRI allows differentiation of different subtypes of RCC by using a multiparametric approach. These sequences can include T1-weighted images, multiplanar T2-weighted sequences (with and without fat suppression), dynamic contrast-enhanced (DCE) sequences (with arterial, corticomedullary, nephrogenic, and excretory phases), diffusion-weighted images (DWIs) (with corresponding apparent diffusion coefficient [ADC] maps), and CSI. Using these unique features, we are better able to differentiate the subtypes of renal masses compared with CT imaging.

Renal cell carcinoma clear cell type (ccRCC) is the most common type of RCC. It is characterized by a heterogeneous high signal on T2-weighted sequences because of the presence of hemorrhage, necrosis, and/or cysts (Pedrosa and Chou, 2008). Papillary RCC (pRCC), when compared with ccRCC, exhibits a homogenous lower signal intensity on T2-weighted images, which is secondary to hemosiderin deposition (histiocytes) within the tumor (Pedrosa and Chou, 2008) (Fig. 3.27). Hemorrhagic cysts with an enhancing peripheral wall growth and/or a solid hypoenhancing mass with low signal intensity (SI) on T2-weighted images resulted in 80% sensitivity and 94% specificity in differentiating pRCC from other types of RCC (Fig. 3.28) (Pedrosa and Chou, 2008).

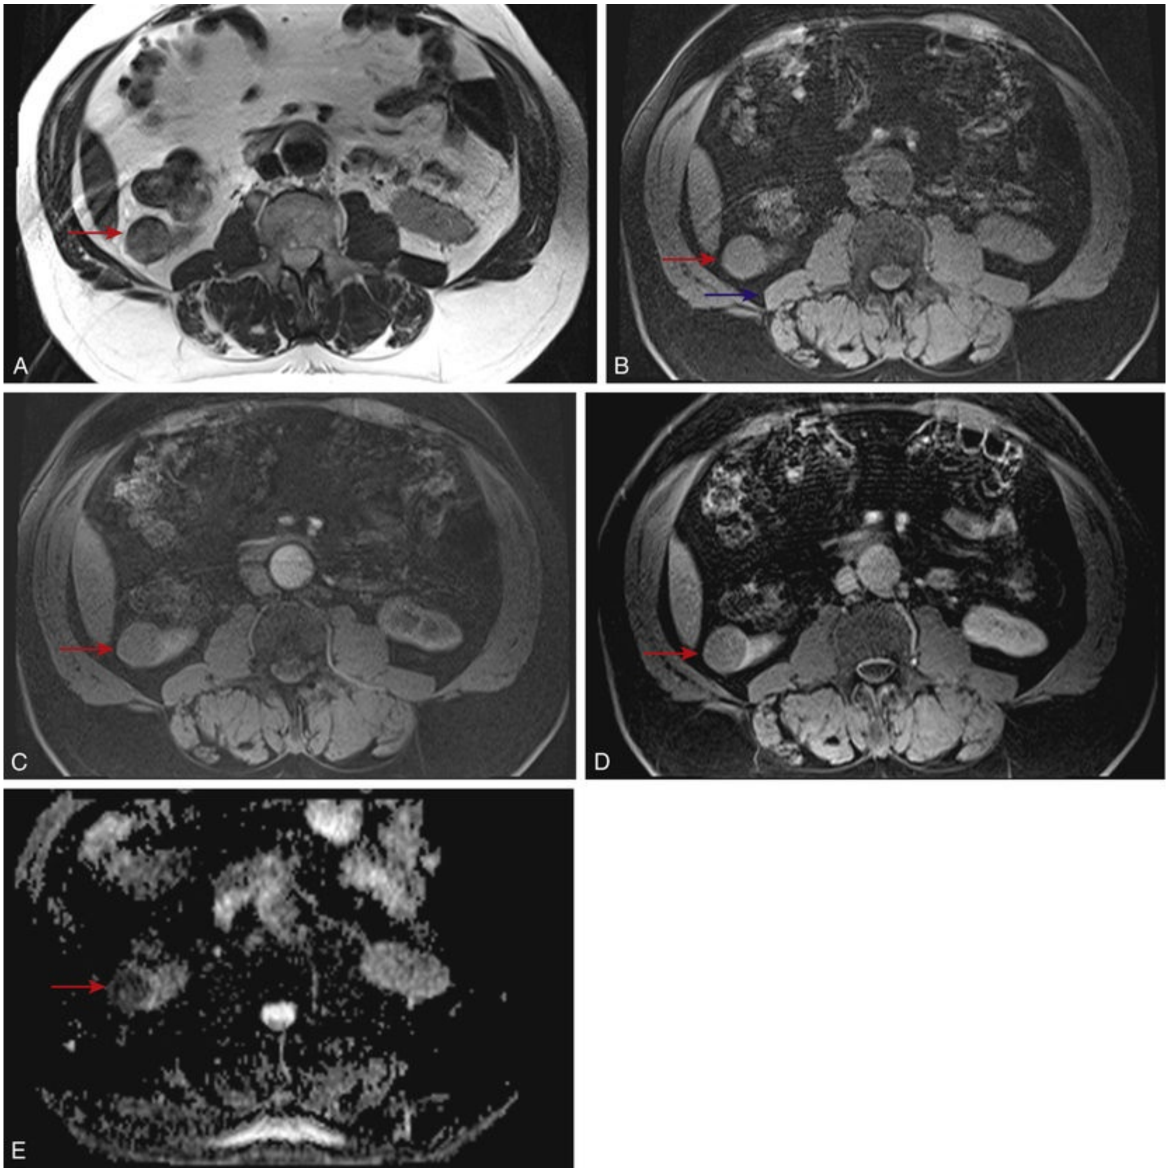

FIG. 3.27 A 72-year-old man with papillary renal cell carcinoma underwent a 1.5T MRI of the abdomen. (A) T2-weighted single-shot fast spin echo image reveals a heterogeneous but primarily low signal intensity of the right renal nodule *(red arrow).* (B) T1 fat-suppressed precontrast images of the right renal nodule with signal isointense to muscle *(blue arrow).* (C) T1 fat-suppressed postcontrast cortical medullary phase with no significant enhancement. (D) T1 fat-suppressed postcontrast nephrogenic phase demonstrates minimal central enhancement. (E) Apparent diffusion coefficient map with low signal intensity of the renal nodule.

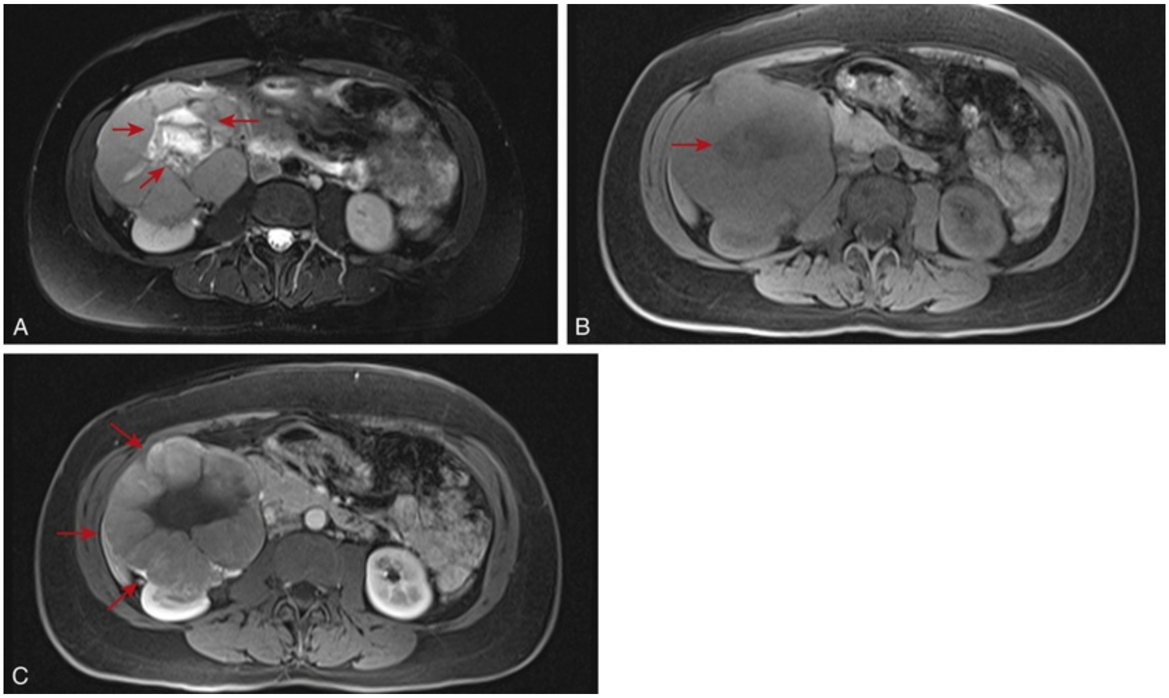

FIG. 3.28 A 45-year-old woman with chromophobe carcinoma with select images from 1.5T MRI of the abdomen. (A) T2-weighted images demonstrate a heterogeneous right renal mass with a high signal intensity centrally *(red arrows).* (B) T1-weighted fat-suppressed precontrast image reveals a central low signal intensity *(red arrow)* and peripheral iso-intensity. (C) T1-weighted fat-suppressed postcontrast image demonstrates peripheral enhancement of the renal mass *(red arrows)* with lack of enhancement centrally.

Similar to adrenal MRI, CSI can detect intracytoplasmic lipids and aid in the differentiation of ccRCC from other RCC subtypes (see Fig. 3.26). Microscopic intracytoplasmic lipids have been found in 59% of clear cell carcinomas (Outwater and Bhatia, 1997). Karlo and Donati reported that once angiomyolipomas (AMLs) have been ruled out using standard MRI techniques (Fig. 3.29) in which macroscopic fat has been detected, chemical shift MR sequences with a 25% decrease in SI can be considered diagnostic for ccRCC from other renal tumors (Karlo and Donati, 2013). Pedrosa and Chou (2008) reported the sensitivity and specificity CSI for ccRCC were 42% and 100%, respectively. There are rare cases of RCC with macroscopic fat; however, if calcifications are also present, this would favor the diagnosis of RCC over AML (Wasser and Shyn, 2013).

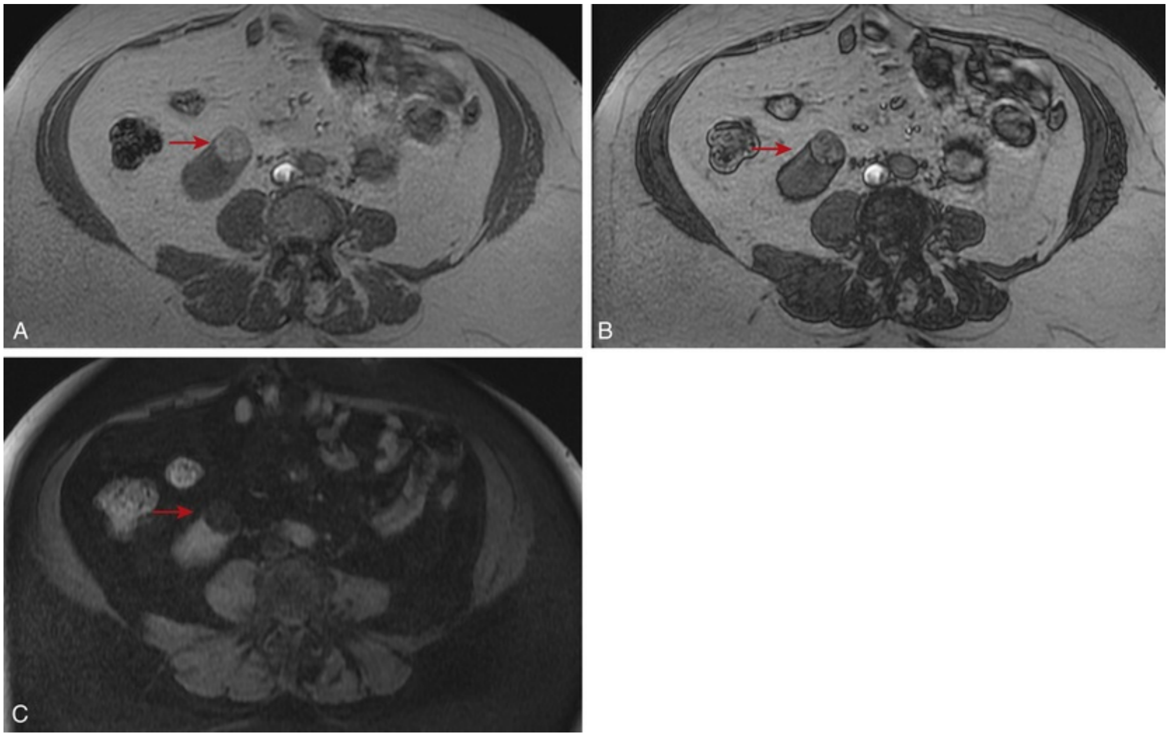

FIG. 3.29 A 78-year-old woman with a 2.5-cm angiomyolipoma with select images from a 1.5T MRI of the abdomen. (A) T1 in-phase right renal nodule *(red arrow).* (B) T1 out-of-phase imaging demonstrating no drop in signal intensity *(red arrow).* (C) T1 fat-suppressed precontrast demonstrates drop in signal intensity within the lesion consistent with macroscopic fat.

Gd-enhanced T1-weighted images with a relative signal intensity increase of 15% is considered to be positive for enhancement, which results in a 100% sensitivity in differentiation cysts from renal cell carcinoma with peak enhancement occurring at 2 to 4 minutes (Ho and Allen, 2002). Using the specific characteristics of DCE MR sequences, Vargas and Chaim assessed the enhancement characteristics of ccRCC, pRCC, AML, and chromophobe carcinoma in the corticomedullary, nephrogenic, and excretory phases (Vargas and Chaim, 2012). Clear cell demonstrated greater than 200% signal intensity increase in all three contrast phases, which was significantly higher than chromophobe and papillary carcinoma (Table 3.6). AML was the only renal mass to demonstrate a decrease in signal intensity from the corticomedullary phase to the nephrogenic phase. Because of a high degree of overlap it is difficult to assign cutoff points. It was not possible to find characteristics to differentiate oncocytoma from ccRCC (Vargas and Chaim, 2012).

TABLE 3.6

MRI Characteristics of Renal Masses

	SIGNAL INTENSITY % CHANGE			AD B VA 0 A 800 s/m 10^{-6} mm
	CORTICOMEDULLARY PHASE	**NEPHROGENIC PHASE**	**EXCRETORY PHASE**	
Clear cell	230%	250%	227%	169
Papillary Carcinoma	49%	92%	88%	884
Chromophobe Carcinoma	98%	183%	159%	113
Oncocytoma	208%	265%	237%	
Angiomyolipoma	353%	285%	222%	
Renal parenchyma				230
TCC				<45

ADC, Apparent diffusion coefficient; *TCC,* transitional cell carcinoma.

Data from Vargas and Chaim, 2012 and Wang et al., 2010.

Oncocytoma typically is described with a central scar, which is observed as a high signal intensity on T2-weighted images. However, this is present in only 54% to 80% of cases (Cornelis and Lasserre, 2013). Unfortunately, a central scar also has been reported in 37% of chromophobe carcinomas (see Fig. 3.28) (Rosenkrantz, 2010). Oncocytoma and chromophobe carcinomas are usually peripheral and are hypovascular compared with the renal cortex (Rosenkrantz, 2010). Necrosis has a high SI on T2-weighted images and low SI on T1-weighted images, which is the same for the central scar associated with oncocytoma (Harmon and King, 1996).

Diffusion-weighted imaging (DWI) detects the restricted movement of water protons within the intra- and extracellular spaces. Wang et al. reported on using an ADC map threshold of 1281×10^{-6} mm^2/s and above for differentiating ccRCC from non-clear cell carcinomas with a 95.9% sensitivity and 94.4% specificity (Table 1 in Wang et al., 2010). Central RCC can be differentiated from transitional cell carcinoma (TCC) of the renal pelvis by setting a threshold of 451×10^{-6} mm^2/s and below on normalized ADC values, resulting in an 83% sensitivity and 71% specificity for detecting TCC (Wehrli and Kim, 2013). It is important to be aware that the calculated ADC map values can vary depending on b-values and TE used for calculation during a specific study (Schmidt et al., 2015). Therefore individual institutional validation of cutoffs may be necessary.

Historically, MRI has been reported superior to earlier CT imaging techniques when attempting to assess if tumor thrombus is present within the renal vein or inferior vena cava. Currently, MRI and CT have the same performance when evaluating for tumor thrombus (Hallscheidt and Fink, 2005). **GBCA is used to differentiate tumor thrombus, which exhibits enhancement, compared with a bland thrombus (clot) which exhibits no enhancement.**

MR and CT can be used to detect and assess lymphadenopathy. Several investigators have been evaluating the use of nanoparticles that are composed of supraparamagnetic iron oxide in the evaluation of lymphadenopathy (Eisner and Feldman, 2009). Normal lymph nodes take up the iron oxide particles via phagocytosis, which results in a signal loss on T2-weighted sequences. Overall, multiparametric MRI (mpMRI) can add important information regarding the tumor microenvironment, which may improve the diagnostic process in evaluating renal masses (see Table 3.6).

Upper Tract and Lower Tract Magnetic Resonance Imaging for Transitional Cell Carcinoma

TCC of the upper tract can be assessed by an MR urogram in addition to the standard renal mass MRI techniques. MR urography (MRU) can be used in patients for whom other imaging modalities are contraindicated. MRU is accomplished by using heavily weighted T2 sequences in which fluid/urine have a high signal intensity or T1-weighted images with gadolinium (Chahal and Taylor, 2005). MRU and CTU have the same accuracy in assessing renal obstruction (Silverman and Leyendecker, 2009). Nephrolithiasis/calcification on

MRI has no signal characteristics; therefore it appears as a signal void on imaging. Urothelial tumors, blood clots, gas, or sloughed renal papilla may exhibit a low signal or signal voids on T2-weighted images secondary to the high signal of urine (Kawashima and Glockner, 2003). Short acquisition times (approximately 2 seconds per image) can be used to differentiate areas of pathology versus ureteral peristalsis (de Leon et al., 2016).

MRI is advantageous over CT imaging of the bladder because of the increased signal contrast between the layers of the bladder. This allows for differentiation between invasive and superficial bladder cancer with an accuracy of 85% (Fig. 3.30) (Tekes and Kamel, 2005). However, bladder underdistention can lead to false negatives during imaging.

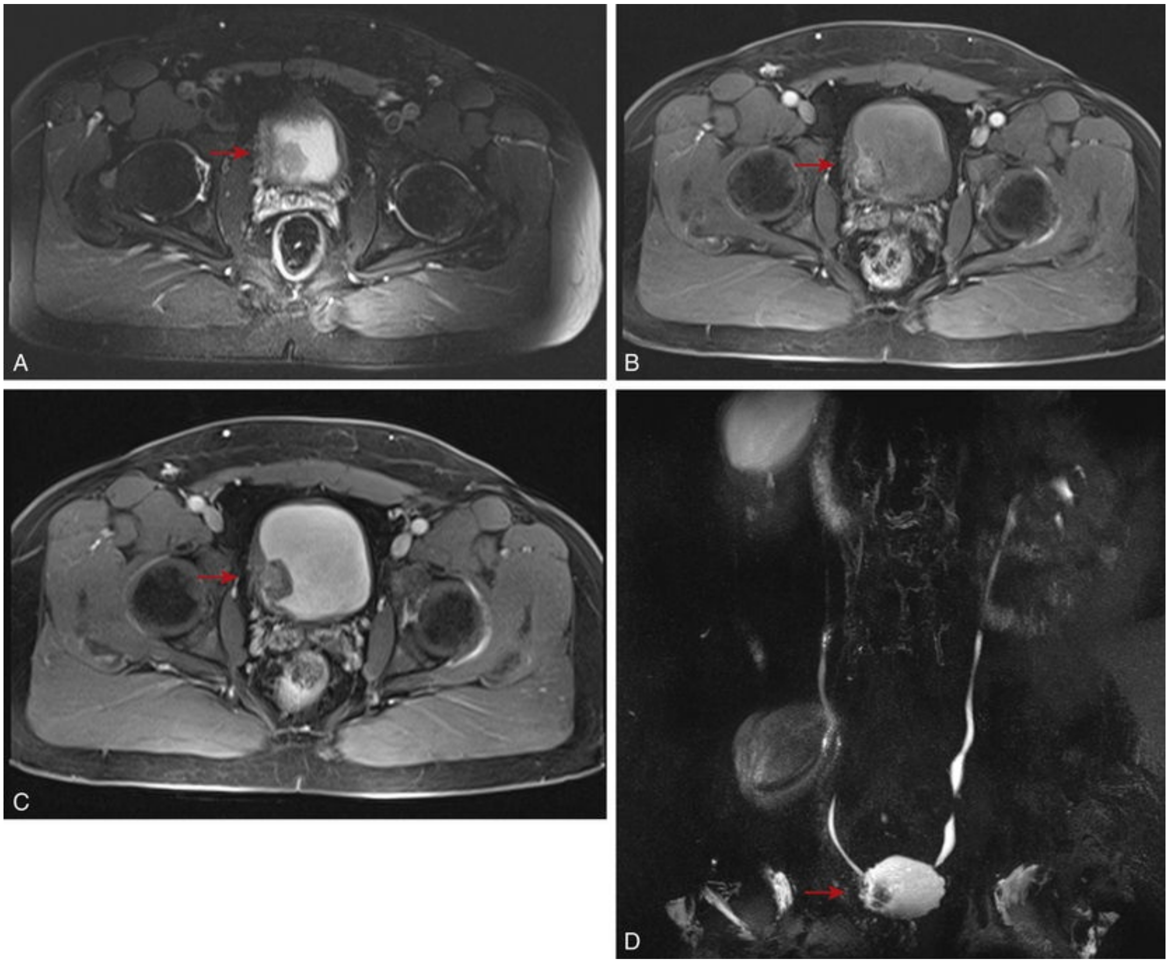

FIG. 3.30 A 51-year-old man with a history of gross hematuria underwent a 1.5T MR urogram. (A) T2 fat-saturated sequence with high T2 signal in bladder (urine). Right bladder wall low signal intensity filling defect *(red arrow).* (B) Fat-suppressed T1 postcontrast arterial phase shows

enhancing right bladder wall polypoid mass and is without bladder wall invasion. (C) Fat-suppressed T1 delayed contrast imaging shows high signal in bladder consistent with IV contrast excretion. Mild persistent signal in right bladder wall mass. (D) Heavily weighted T2 MRI urogram selectively demonstrates high signal of fluid within the ureters and bladder. Right wall bladder filling defect is evident. TURBT confirmed no bladder wall invasion of a high-grade papillary urothelial carcinoma.

Prostate Magnetic Resonance Imaging

Prostate cancer (CaP) is one of the last solid organ malignancies lacking reliable and reproducible imaging, thus leaving urologists to rely on ultrasound as the primary imaging modality and an extended sextant (12 to 14 core) biopsy as the standard of care when assessing a man's risk of CaP. In the last 15 years, several developments have led to the integration of MRI for the detection of CaP. Some of these advances include an increase in the field strength (Tesla) of magnets from 1.0 Tesla (T) to 3T, improved imaging protocols, and surface coils, which resulted in an increase in signal contrast (signal-to-noise ratio [SNR]), allowing for improved visualization and differentiation of normal versus abnormal prostate tissue. The PROMIS study (2017) reported level 1b evidence supporting the use of MRI as a screening tool to be used before prostate biopsies in patients with an elevated PSA (Ahmed et al., 2017). A follow-up study demonstrated that this new approach could be cost effective (Faria, 2018). This was followed by the Goteborg Swedish screening study demonstrating an approximate 50% decrease in biopsies if prostate MRI was used in a screening protocol with a PSA threshold of 2.8 ng/mL. However, even with this supporting data and advances in MRI technology, mpMRI is still not considered a standard of care and therefore not always covered by insurance carriers. The AUA issued guidance (2017) on the use of mpMRI and reported that the evidence available did not fully support the use of mpMRI in all men with an elevated PSA. The current recommendations are reserved for staging a known CaP and patients with a prior negative prostate biopsy (Fulgham, 2017).

Several authors have reported on varying standards that should be used for prostate imaging. The currency in MRI is signal. Signal detection is optimized by using external surface coils and/or an endorectal coil (ERC) and therefore leads to improved image quality. The National Institutes of Health (NIH) completed a study comparing the diagnostic accuracy at 3T with and without ERC in the same patients and compared findings with whole mount histopathology. Results indicated a 36% decrease in sensitivity in detecting CaP when the ERC was not used (Turkbey and Mani, 2013). Follow-up studies by the ACR demonstrated that not all radiology practices have integrated the standards set forth by the PIRAD v2 document (Weinreb and Barentsz, 2016). Urologists must become more informed and ask their radiology partners to optimize imaging and use standardized reporting to improve patient care.

Prostate MRI usually is referred to as an mpMRI, which consists of anatomic and functional imaging techniques. Anatomic imaging should include T1- and T2-weighted images. Functional imaging includes DWI with ADC maps, DCE sequences, and possibly spectroscopy. MR spectroscopy is not always included in the standard mpMRI sequences. MR spectroscopy takes approximately 15 minutes to perform, is labor intensive, and may not add additional information to affect the clinical interpretation of the study.

Initial T1-weighted sequences are obtained to determine if hemorrhage is present within the prostate and, if present, may limit the diagnostic interpretation of the study. If hemorrhage is present, it can lead to false positives on T2-weighted sequences, DWI/ADC, and DCE images, although some authors report no difference in diagnostic accuracy with or without hemorrhage present (Rosenkrantz, 2010). There is debate regarding the time between biopsy and the prostate MRI. A prostate MRI can be performed 3 to 8 weeks after a biopsy to optimize intraprostatic anatomy (Ikonen, 2001; Muller, 2014; Qayyum and Coakley, 2004). The wait period is not required for presurgical staging to determine if there is extraprostatic extension (EPE) and/or seminal vesicle invasion (SVI).

The AUA guidance on mpMRI of the prostate does recommend a minimum exam should be a 1.5T MRI with an ERC or a 3T with or without an ERC and a multiparametric approach (Fulgham, 2017). The use of external phased array coils increases signal detection and therefore improves image quality. A 3T mpMRI with a minimum of 16 to 32 channels phased array coil and an ERC detects the highest signal and therefore provides the highest-quality images (spatial and temporal resolution). However, it is unclear if a radiologist needs this level of quality to make a diagnostic impression. An ERC should never be filled with air or water (Rosen and Bloch, 2007). This causes a decrease in the performance of the T2, DWI, and MR spectroscopy. The most optimal fluids are diamagnetic and proton neutral (Rosen and Bloch, 2007). In patients with metallic implants, alternative scanning protocols may be used, which includes the use of 1.5T scanners or specific 3T protocols for patients with pacemakers.

T2-Weighted Imaging

T2-weighted sequences of the prostate provide anatomic information and should include a triplanar (axial, coronal, and sagittal) or comparable sequence (Fig. 3.31). These images provide a detailed anatomic assessment of the gland. The normal peripheral zone appears as an area of high signal intensity. The central gland with BPH appears as areas of well-demarcated nodules with a heterogeneous signal intensity. Areas of low signal intensity on T2-weighted sequences can represent CaP or prostatitis, atrophy, scars, postprostate biopsy hemorrhage, and/or BPH nodules (Barentsz and Richenberg, 2012). BPH nodules (stromal proliferation) can also be observed within the peripheral zone and can result in a false-positive MRI for cancer (see Fig. 3.31).

FIG. 3.31 A 66-year-old African-American man with a prostate-specific antigen (PSA) of 7.0 and two prior negative biopsies. A 3T mpMRI with an endorectal coil of the prostate was obtained. There were two suspicious areas. A, D, and E are the triplanar axial, sagittal, and coronal plane images. The peripheral zone *(blue line)* and the central gland *(yellow arrow)* are well visualized. The *red arrow* represents a well-circumscribed heterogeneous BPH nodule (11 mm × 11 mm × 14 mm) within the peripheral zone with no communication to the central gland. The corresponding apparent diffusion coefficient map (B) demonstrates areas of heterogeneous restriction (761 × 10^{-6} mm^2/s). The lesion on the dynamic contrast-enhanced (DCE) image (C) exhibits focal type 2 and 3 enhancement curves. (F) The DCE quantitative analysis is listed. The patient underwent a fusion biopsy. The lesion was also appreciated on US and no cancer was detected.

T2-weighted imaging alone results in a 58% sensitivity and 93% specificity for detecting CaP within the gland at 3T with an ERC (Turkbey and Mani, 2011). These limitations reinforce the need to perform a multiparametric assessment that incorporates functional imaging and increases the NPV and PPV of the exam to greater than 90% (Turkbey and Mani, 2011). T2-weighted sequences are used to assess EPE and SVI. These areas are represented by low signal intensity. mpMRI at 3T with an ERC has an approximate 90% accuracy when assessing extraprostatic extension on a per-lesion analysis. At the patient level, comparing the accuracy of staging, including microscopic EPE, overall accuracy decreased to 78.5% (Turkbey and Mani, 2011). The use of ERC improves the accuracy of detecting EPE and SVI (Heijmink and Fütterer, 2007).

Diffusion-Weighted Imaging/Apparent Diffusion Coefficient Maps

Diffusion-weighted imaging (DWI) assesses the diffusion of water (Brownian motion) within the magnetic field. The MR magnet detects the phase shift changes in the motion of the water protons. The more cellular a tissue is, the closer the cells are together, which results in a limited motion of water that is reflected as a high signal intensity on DWIs (Manenti, 2006).

As with all MR sequences there are several details that warrant observation. Most important are the b-values associated with DWI. b-Values represent threshold for detecting restriction. As a b-value is increased, less restricted tissues do not exhibit a high signal on DWI. DWI can include multiple b-values, and it is recommended to include at least one b-value greater than 1000 (Rosenkrantz and Minnelli, 2011). The ADC is a quantitative assessment of the DWI. This is represented by an area of low signal on the images (dark spot) (Fig. 3.32D). Some authors recommend including a b-2000 sequence on DWI; it has been shown that CaP exhibits a high signal intensity compared with the rest of the gland (Fig. 3.32F) (Ueno and Kitajima, 2013). There has been interest in shortening the image acquisition time by discontinuing DCE from the standard protocol (Jambor, 2017; Scialpi et al., 2016). Rosenkrantz et al. replied to these suggestions and highlighted the pitfalls that could arise with this approach. They recommended against discontinuing the DCE sequence because it can aid in the detection of small lesions, lesions with poor signal contrast with adjoining tissues, and overcome possible artifacts limiting T2 and DWI sequences (Rosenkrantz et al., 2016).

FIG. 3.32 A 65-year-old African-American man with a prostate-specific antigen (PSA) of 38.9 and 16 prior negative biopsies with MR US fusion biopsy proven Gleason 4+4 prostate cancer. (A) T2-weighted image with an anterior lesion within the central gland, 3.5 cm × 2.7 cm × 3.5 cm *(red arrow).* (B and H) Dynamic contrast-enhanced MR sequence with color mapping exhibiting a focal type 3 enhancement curve. (C) Elevated K_{trans}. (D) Apparent diffusion coefficient map with low signal. (E) Elevated K_{ep}. (F) Area under the curve (AUC). (G) b-2000 Diffusion-weighted sequence with an area of high signal intensity. (I) Quantitative summary of the large anterior central gland lesion.

The ADC value computed from the DWI has been shown to correlate directly with the Gleason score (Turkbey and Mani, 2011). Intuitively this makes sense, as an increase in cellularity results in an increase in the Gleason score. The extracellular/intracellular spaces between the cells are decreased and therefore reflected as areas of increased restriction.

Dynamic Contrast-Enhanced Magnetic Resonance Imaging

DCE MRI is T1-weighted imaging with Gd-based contrast agents. DCE is not a simple assessment of enhancement versus no enhancement. DCE MRI assesses vascular permeability and perfusion of the prostate by obtaining multiple image acquisitions over 5 to 10 minutes at a temporal resolution of less than or equal to 5 seconds (Verma and Turkbey, 2012). The 5-second temporal resolution requires a decrease in the size of the imaging matrix, resulting in a “lower-resolution image.” DCE MRI is not meant to obtain clear anatomic images, and it is used to assess the blood flow and vascular permeability throughout the gland over time.

DCE provides qualitative, semiquantitative, and quantitative information regarding enhancement within the prostate. A qualitative approach consists of visually assessing early enhancement and early washout within the prostate. The use of computer-aided diagnostic systems provides specific information regarding enhancement characteristics. A semiquantitative approach assesses enhancement over time (Verma and Turkbey, 2012). There are three distinct curves associated with prostate imaging (Fig. 3.33). Because of the overlap of all three curve types with benign conditions, it is useful to combine these approaches in mpMRI. A quantitative assessment for cancer was first proposed by Tofts and Wicks observing the pharmacokinetics of the contrast within the gland (Tofts and Wicks, 1991). K_{trans} (transfer constant) represents the transfer rate (permeability) of contrast between the intravascular space and the extracellular space (or blood flow) to the tissues depending on the hemodynamics at the time of the study (Tofts and Brix, 1999). K_{ep} (rate constant) is the rate of efflux of contrast back into the vascular space (Tofts and Brix, 1999). These quantitative metrics have not been incorporated in the daily work flow of most radiologists; however, they are being evaluated for possible decision analysis software (see Fig. 3.32C, D, E, and H).

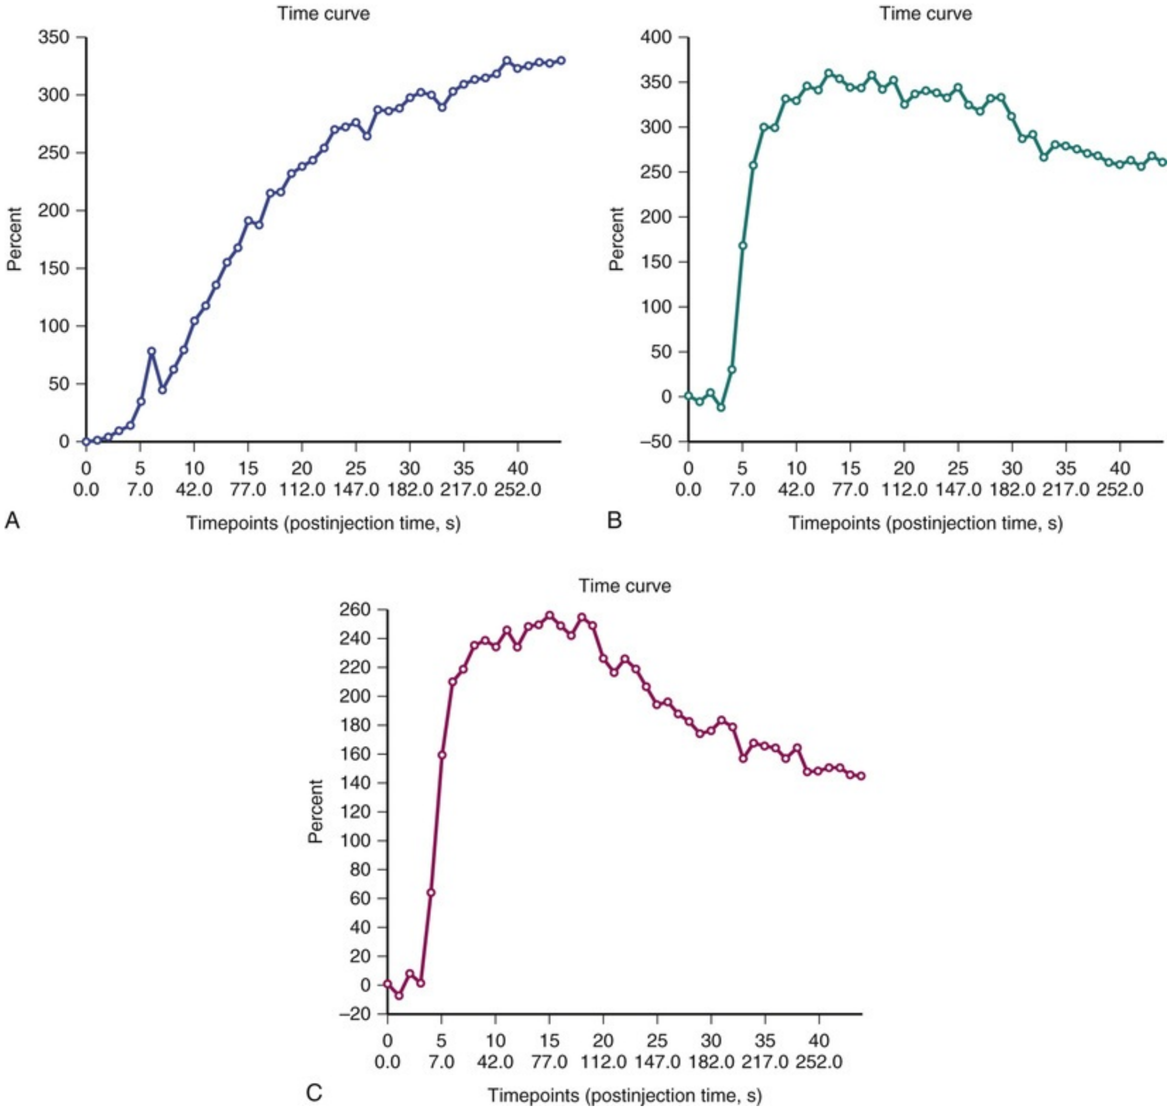

FIG. 3.33 (A) Type 1 curve is normal enhancement with persistent increase in enhancement over time. (B) Type 2 curve is early enhancement with a plateau (no washout). (C) Type 3 curve, which is the most indicative of prostate cancer, can overlap with inflammation and this is characterized by early enhancement with an early washout of contrast.

DCE MRI has a reported 46% to 96% sensitivity and 74% to 96% specificity for detecting CaP. These large ranges can be due to the high variability resulting from patient selection, MRI technique, and pathology correlation and reader experience (Verma and Turkbey, 2012).

Magnetic Resonance Spectroscopy

Proton MR spectroscopic imaging (MRSI) detects the concentration of citrate, choline, and creatine within the prostate. As cells go through malignant transformation, citrate decreases, and creatine and choline levels increase secondary to increased cellular turnover (Choi, 2007). An increase of 2 standard deviations of choline-to-citrate ratio is indicative of cancer (Kurhanewicz, 1996). This process is time consuming (15 minutes) and has fallen out of favor when used in a nonresearch setting. Turkbey and Mani reported only a 7% increase in PPV and NPV using MRSI (Turkbey and Mani, 2011). Therefore the additional time may not clinically affect cancer detection rates. There is still a significant research potential associated with MRSI. Some authors are using MRSI assessment cellular metabolism (choline, creatine, and citrate) to evaluate biochemical recurrence after radiation therapy (Zhang and Westphalen, 2014).

Multiparametric Magnetic Resonance Imaging

The combination of T2, DCE, and DWI has yielded NPV and PPV greater than 90% (Abd-Alazeez and Kirkham, 2014; Turkbey and Mani, 2011). It is important to understand that high-quality MRI requires tuning of the MR magnets, a dedicated staff to perform the studies, and pathology correlation for the urologists/radiologists. There are thousands of adjustable settings to obtain high-quality images. It is important to start with the basics, which are outlined in the most recent *Prostate Imaging: Reporting and Data System V2* from the ACR (Weinreb and Barentsz, 2016). If an ERC is used during the study, an antispasmodic agent should be used to decrease the artifact created by rectal spasms. The MR technologist should actively review images during the study and adjust or repeat sequences as needed. Using newer magnets with higher field strength, external coils, and an ERC can decrease image acquisition time and may improve image quality (Fig. 3.34) (Heijmink, 2011).

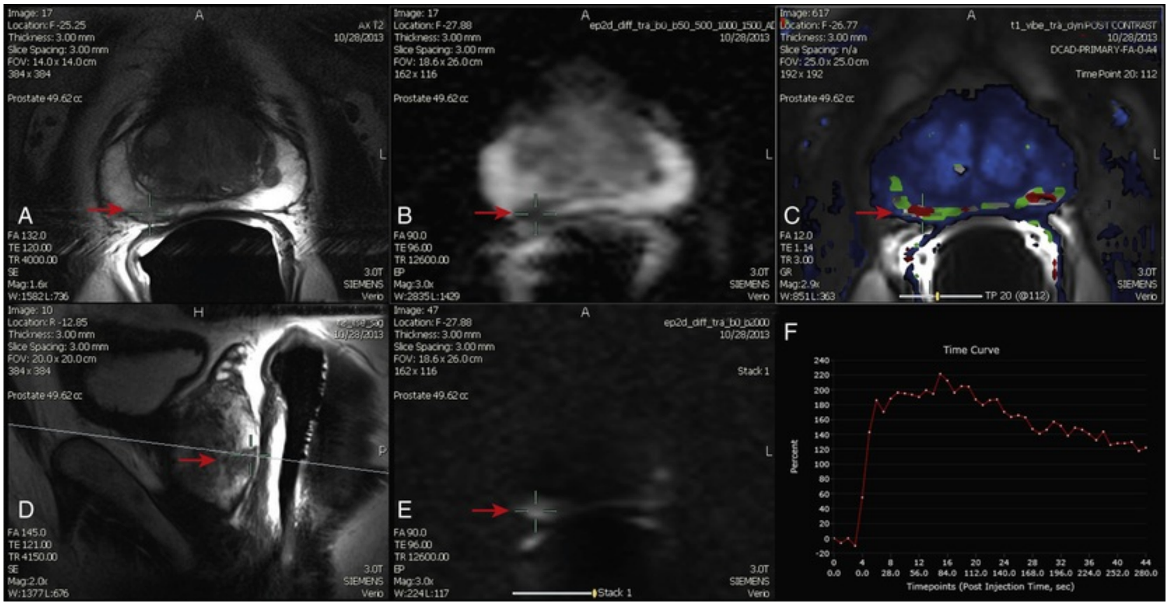

FIG. 3.34 A 61-year-old Caucasian man with an increasing prostate-specific antigen (4.65 ng/mL) after a prior negative biopsy 1 year ago. 3T mpMRI of the prostate with an endorectal coil was obtained. (A) T2-weighted image with a homogeneous low signal intensity lesion within the right posterior peripheral zone *(red arrow).* (B) Apparent diffusion coefficient (ADC) map with a corresponding low signal intensity to the T2 sequence. (C) Dynamic contrast-enhanced **(**DCE) MRI with color mapping exhibiting a focal type 3 enhancement curve. (D) Sagittal T2 sequence with a low signal lesion within the peripheral zone. (E) b-2000 Diffusion-weighted image with high signal corresponding to T2, ADC, DCE abnormalities. (F) Type 3 enhancement curve. The pathology was Gleason 3+4 prostate cancer, zone 3L, volume was 0.3 cc (9 × 8 × 9 mm).

As more and more physicians begin to use mpMRI of the prostate (Fig. 3.35), maintaining quality and improving interpretation is extremely important. Each center should have designated readers. Prostate MRI is like no other study in radiology and can benefit from consensus reading and pathology correlation, especially when an imaging program is established (Muller, 2013). The PIRADS v2 has given guidance to standardize zonal reporting, which helps urologists use information from the report regarding slice #2 on T2-weighted sequence and zonal location to identify suspicious areas (Table 3.7).

PIRADS v2 Assessment Categories

1 **Very Low**: Clinically significant disease is highly unlikely to be present.

2 **Low:** Clinically significant disease is unlikely to be present.

3 **Intermediate**: Clinically significant disease is equivocal.

4 **High**: Clinically significant disease is likely to be present.

5 **Very High**: Clinically significant disease is highly likely to be present.

From Barentsz JO, Weinrebb JC, Verma S, et al: Synopsis of the PI-RADS v2 Guidelines for Multiparametric Prostate Magnetic Resonance Imaging and

Recommendations for Use, *Eur Urol* 69(1):41–49, 2016.

In summary, mpMRI of the prostate is a potential new tool that can detect, quantify, stage, and influence treatment planning for patients with CaP. mpMRI has also been shown to correctly select patients with low-grade/low-volume disease for active surveillance with an accuracy of 92% (Turkbey and Mani, 2013). mpMRI of the prostate also provides information on possible bone involvement or lymphadenopathy at the time of diagnosis. The accuracy of MRI detecting lymphadenopathy has a sensitivity up to 86% and specificity of 78% to 90% (Talab and Preston, 2012). It is important that scanning parameters and updates from the American College of Radiology are observed and integrated as best as possible.

Magnetic Resonance Fusion-Guided Prostate Biopsy

MR US fusion-guided prostate biopsy is the next step in the integration of high-quality intraprostatic imaging in the urologist armamentarium for screening and diagnosing CaP. There are multiple fusion biopsy systems on the market. The performance of these systems does differ slightly from one vendor to the other. However, the most important factor is the quality of the mpMRI and abilities of the imaging team. These two factors have been shown to result in increased cancer detection rates in patients undergoing targeted biopsies (Pinto and Chung, 2011; Siddiqui et al., 2015; Sonn and Natarajan, 2013).

Currently, a targeted biopsy or mpMRI alone is not an alternative to the standard of care in screening men for CaP. mpMRI offers a distinct advantage when selecting men to undergo a biopsy with an elevated PSA. PSA is not CaP-specific and can be elevated because of numerous reasons, including inflammation/infection, BPH, and/or physical manipulation. The MRI can assess BPH and inflammation before a biopsy; this may allow men with a persistently elevated PSA and an initial negative 12-core biopsy to avoid undergoing a second biopsy. In addition, mpMRI of the prostate can detect intermediate and high-risk disease but has difficulty detecting low-grade/low-volume cancers, which may decrease overdiagnosis and overtreatment of clinically insignificant disease. Moore et al. reported that 38% of men with an elevated PSA did not have any visible lesions on mpMRI. In this study, a 12-core biopsy only detected clinically significant cancer for 2.3% of the patients (Gleason ≥7 or a core length of >5 mm) (Moore, 2013).

The MR US fusion-guided biopsy has the advantage of using the MRI to target specific areas (i.e., anterior or central gland lesions) within the prostate that may be missed or undersampled on a standard systematic 12-core biopsy. In addition, the 12-core biopsy may miss many lesions within the peripheral zone.

The cancer detection rates for targeted biopsies is superior compared with a cognitive biopsy in which one uses the information from the MRI for freehand targeting (Wysock, 2014). The CDR rate for fusion-targeted biopsies with moderate to high suspicion on mpMRI is approximately 50% to 72% (Pinto and Chung, 2011; Rastinehad and Turkbey, 2014; Sonn and Natarajan, 2013).

For more information, see Chapter 151.

Key Points: Magnetic Resonance Imaging

- When a renal mass is seen on MRI, the most important characteristic indicating the presence of a malignancy is enhancement of the mass.
- NSF is seen in patients with severe renal insufficiency who are exposed to gadolinium contrast media.
- Pheochromocytoma, metastatic lesion to the adrenal gland, and primary adrenal cortical carcinoma are bright on T2-weighted images.

Acknowledgments

Thank you to the Drs. Ben-Levi, Villani, and Friedman for their help acquiring and reviewing images.

Urinary Tract Imaging

Basic Principles of Urologic Ultrasonography

Bruce R. Gilbert MD, PhD, Pat F. Fulgham MD

Ultrasound has often been referred to as the urologist's stethoscope because much of the genitourinary system is not easily evaluated by physical examination and requires imaging for diagnosis. Therein lies one of the unique aspects of ultrasound studies performed and interpreted by urologists. The mandate to examine the patient, coupled with the urologist's experience in surgical and medical treatment, engenders an unparalleled ability to meld the healer's art with advanced imaging technology. In addition, ultrasonography is a versatile and relatively inexpensive imaging modality that has the unique feature of being the only imaging modality to provide real-time evaluation of urologic organs and structures without the need for ionizing radiation. For urologists to best use this technology on behalf of their patients, they must have a mature understanding of the underlying physical principles of ultrasound. They must also understand how the manipulation of ultrasound equipment can affect the quality of ultrasound images. The technical skills required to perform and interpret urologic ultrasonography represent a combination of practical scanning ability and knowledge of the underlying disease process in organs being imaged. To communicate the findings appropriately, urologists should understand the nomenclature of ultrasonography and have a specific plan for documentation of each type of study. Understanding how ultrasonography interacts with human tissues allows urologists to use this modality effectively, appropriately, and safely. It is our fervent hope that this chapter may encourage many urologists to embrace the art and science of ultrasound in their mission to provide excellence in patient care (▶Video 4.1).

Brief History of Ultrasound in Urology

In 1963 Japanese urologists Takahashi and Ouchi became the first to attempt ultrasonic examination of the prostate. However, the resulting image quality was not interpretable and thus carried little medical utility (Takahashi and Ouchi, 1963). Wild and Reid (1955) also attempted transrectal ultrasound but met with the same result. Progress was not made until Watanabe et al. demonstrated radial scanning that could adequately identify prostate and bladder pathology. Using a purpose-built device modeled after a museum sculpture entitled “Magician's Chair,” Watanabe seated his patients on a chair with a hole cut in the center such that the transducer tube could be passed through the hole and into the rectum of the seated patient (Fig. 4.1A; Watanabe et al., 1974). It is evident in Figs. 4.1B (demonstrating an area of circumscribed symmetric echogenicity representing benign prostatic hyperplasia [BPH]) and 4.1C (demonstrating an asymmetric area of hyperechogenicity, representing prostate cancer) that resolution was poor and images displayed extreme contrast. Subsequent development of biplane, high-frequency probes has created increased resolution and has allowed for transrectal ultrasound to become the standard for diagnosis of prostatic disease.

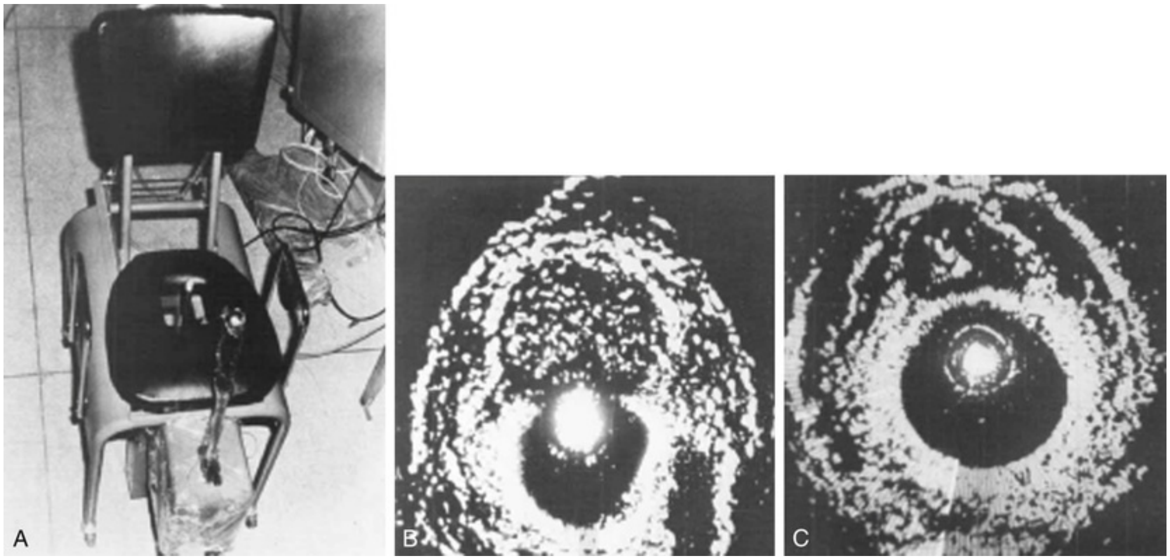

FIG. 4.1 (A) Watanabe's chair; (B) display of patient with BPH; (C) display of prostate cancer. (From Watanabe H et al.: Development and application of new equipment for transrectal ultrasonography. *J Clin Ultrasound* 2[2]:91–98, 1974.)

In 1971 Goldberg and Pollack, frustrated with the inability of intravenous pyelogram (IVP) to differentiate benign from malignant lesions, turned to A-mode ultrasound in the evaluation of the kidney. In their report on “nephrosonography,” they demonstrated in a series of 150 patients the capability of ultrasound to discern solid, cystic, and complex masses with an accuracy of 96%. The diagrammatic representation of the three ultrasound patterns they found are depicted in Fig. 4.2 (Goldberg and Pollack, 2002). In cystic lesions, the first spike represents the striking of the front wall of the cyst, and the second spike represents the striking of the back wall. More complex lesions therefore have return of more spikes.

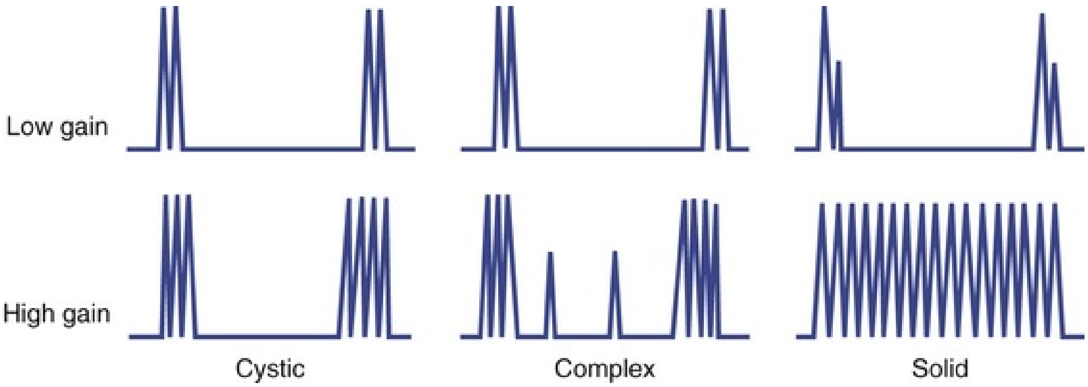

FIG. 4.2 Goldberg and Pollack were the first to differentiate among solid, complex, and cystic masses by ultrasound. In cystic lesions, the first spike represents the striking of the front wall of the cyst, and the second spike represents the striking of the back wall. More complex lesions therefore have return of more spikes. (From Goldberg B, Pollack H: Differentiation of renal masses using A-mode ultrasound. *J Urol* 167[2]:1022–1026, 2002.)

In 1974 Holm and Northeved introduced a transurethral ultrasonic device that would be interchangeable with conventional optics during cystoscopy for the purpose of imaging the prostate and bladder. Their other goals for this device included the ability to determine depth of bladder tumor penetration, prostatic volume, evaluation of prostatic tumor progression, and to assist with transurethral resection of prostate (Holm and Northeved, 1974).

Perri et al. were the first to use Doppler as a sonic “stethoscope” in their workup of patients with an acute scrotum in 1976. Although they were able to identify patients with epididymitis and torsion of the appendix testis as having increased flow and patients with spermatic cord torsion as having no blood flow, they also reported that false negatives in cases of torsion could result from increased flow secondary to reactive hyperemia (Perri et al., 1976).

Watanabe et al., pioneers in the use of ultrasound in urology, demonstrated that Doppler could be used to identify the renal arteries in a noninvasive way in 1976 (Watanabe et al., 1976). Five years later, Greene et al. documented that Doppler could adequately differentiate stenotic from normal renal arteries (Greene et al., 1981). In 1982 Arima et al. used Doppler to differentiate acute from chronic rejection in renal transplant patients, noting that acute rejection is characterized by the disappearance of diastolic phase, with reappearance being indicative of recovery from rejection. The authors concluded that Doppler could guide the management of rejection as an index for steroid therapy (Arima et al., 1982).

In the early 1990s a number of authors investigated the therapeutic uses of high-intensity focused ultrasound (HIFU). After prior reports of histologic changes after HIFU (Burgess, Iwamoto, and Coleman, 1987), Madersbacher et al. were the first to report the safety and efficacy of HIFU in patients with symptomatic BPH (Madersbacher et al., 1993). Its utilities in the treatments of testicular cancer (Madersbacher et al., 1998), early prostate cancer (Chapelon et al., 1999), recurrent prostate cancer (Berge, Baco, and Karlsen, 2010), and renal cell cancer transcutaneously (Köhrmann, Michel, and Gaa, 2002) and laparoscopically (Margreiter and Marberger, 2010) were soon explored.

Novel uses for ultrasound technology continue to be demanded and discovered in the field of urology. Chen et al. (2010) used transrectal ultrasound guidance to inject botulinum toxin into the external urethral sphincters of a series of patients with detrusor external sphincter dyssynergia. Ozawa et al. used perineal ultrasound video-urodynamics to accurately diagnose bladder outlet obstruction in a new, noninvasive method (Ozawa, Igarashi, and Uematsu, 2010). The possibilities for the application of ultrasound in diagnosing or treating urologic patients are endless.

Urologic ultrasound continues to evolve with the use of contrast agents and new modalities (e.g., sonoelastography), which include groundbreaking discoveries and new applications of basic physical principles. This homage to the innovators of the past recognizes prior achievements and acknowledges that future work in the development of new applications for ultrasound will always be needed.

Physical Principles

All ultrasound imaging is the result of the interaction of sound waves with tissues and structures within the human body. Ultrasound waves are produced by applying short bursts of alternating electrical current to a series of crystals housed in the transducer. Alternating expansion and contraction of the crystals via the piezoelectric effect creates a mechanical wave that is transmitted through a coupling medium to the skin and then into the body. The waves that are produced are longitudinal waves. In a longitudinal wave the particle motion is in the same direction as the propagation of the wave (Fig. 4.3). This motion produces areas of rarefaction and compression of tissue in the direction of travel of the ultrasound wave (Fig. 4.4). A portion of the wave is reflected toward the transducer. The transducer then serves as a receiver and "listens" for the returning sound wave reconverting the mechanical to electrical energy. The transducer must be in direct, secure contact with the subject to transmit and receive the reflected sound waves.

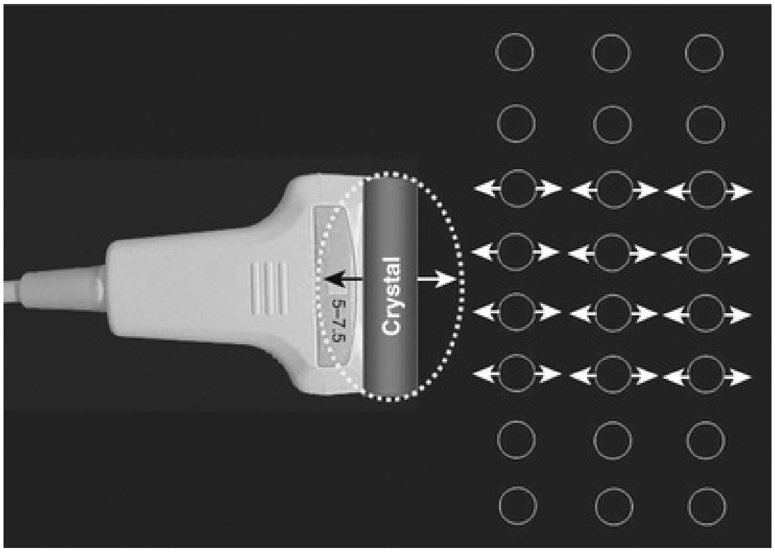

FIG. 4.3 The alternating expansion and contraction of the crystal produces longitudinal mechanical waves. In this simplified schematic drawing, the individual molecules *(depicted as circles)* are displaced in the direction of the propagated wave.

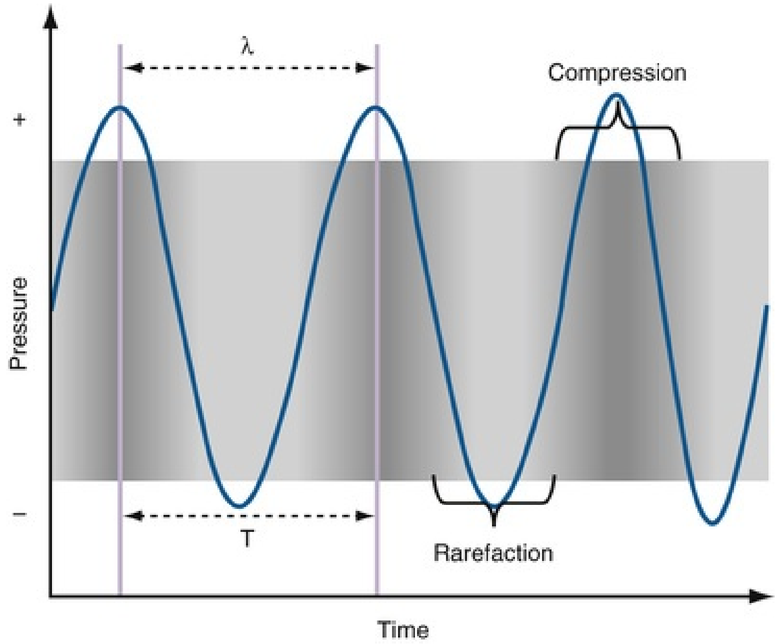

FIG. 4.4 Areas of compression alternating with areas of rarefaction are depicted as a sine wave. The wavelength *(λ)* is the length from peak compression to peak compression in this drawing. This graphic depiction is critical to the understanding of the behavior of sound waves in the human body and of how ultrasound images are generated. (From Merritt CRB: Physics of ultrasound. In Rumack C, Wilson S, eds: *Diagnostic ultrasound,* ed 3, St. Louis, 2005, Elsevier.)

The appearance of the image produced by ultrasonography is the result of the interaction of mechanical ultrasound waves with biologic tissues and materials. Because ultrasound waves are transmitted and received at frequent intervals, the images can be rapidly reconstructed and refreshed, providing a real-time image. The frequencies of the sound waves used for urologic ultrasound imaging are in the range of 3.5 to 20 MHz.

Mechanical waves are represented graphically as a sine wave alternating between a positive and negative direction from the baseline. In the case of ultrasound, the amplitude of the sine wave describes differences in pressure. Ultrasound waves are described using the standard nomenclature for sine waves. A wavelength (λ) is described as the distance between one peak of the wave and the next peak. The complete path traveled by the wave from one peak to the next is called a *cycle*. One cycle per second is known as *1 hertz* (Hz). The "period" is the time it takes for one complete cycle of the wave.

The "amplitude" of a wave is the maximal excursion in the positive or negative direction from the baseline. Amplitude corresponds to the mechanical energy associated with the sound wave and is a key property in assigning pixel brightness to a gray-scale ultrasound image. The greater the amplitude is, the brighter the corresponding pixel.

Ultrasound Image Generation

The image produced by an ultrasound machine begins with the transducer. In ultrasound imaging, the transducer has a dual function as a sender and receiver. Sound waves are created in short pulses and transmitted into the body and are then at least partially reflected. Reflected mechanical sound waves are received by the transducer and converted back into electrical energy. The transducer acts as a receiver more than 99% of the time. The electrical energy is converted by the ultrasound instrument to an image displayed on a monitor (Fig. 4.5).

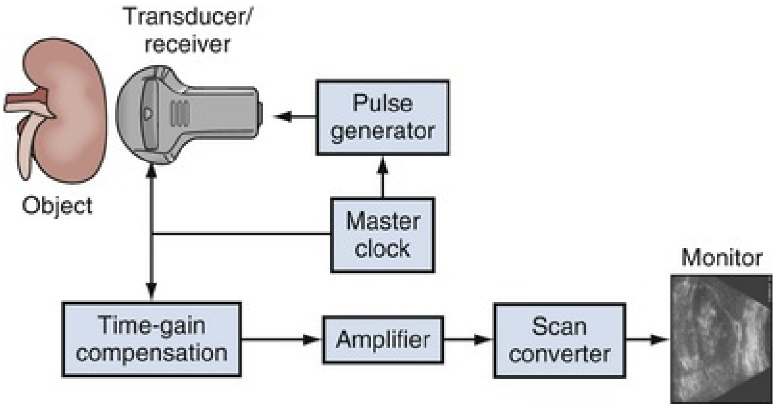

FIG. 4.5 In this simplified schematic diagram of ultrasound imaging, the ultrasound wave is produced by a pulse generator controlled by a master clock. The reflected waves received by the transducer are analyzed for amplitude and transit time within the body. The scan converter produces the familiar picture seen on the monitor. The actual image is a series of vertical lines that are continuously refreshed to produce the familiar real-time, gray-scale image.

Resolution

The resolution of an ultrasound image refers to the ability to discriminate between two objects that are close to one another. **Axial resolution** refers to the ability to identify as separate two objects in the direction of the traveling sound wave. Axial resolution is directly dependent on the frequency of sound waves. The higher the sound wave's frequency is, the better the axial resolution. **Lateral**

resolution refers to the ability to identify separately objects that are equidistant from the transducer. Lateral resolution is a function of the focused width of the ultrasound beam and is a characteristic of the transducer. The location of the narrowest beam width can be adjusted by the user. The more focused the beam is, the better the lateral resolution at that location. Thus image quality can be enhanced by locating the narrowest beam width (focus or focal zone) at the depth of the object or tissue of interest (Fig. 4.6). Continued improvements in transducer design and software allow for near-simultaneous beam steering, multiple foci, and focusing in the azimuthal plane.

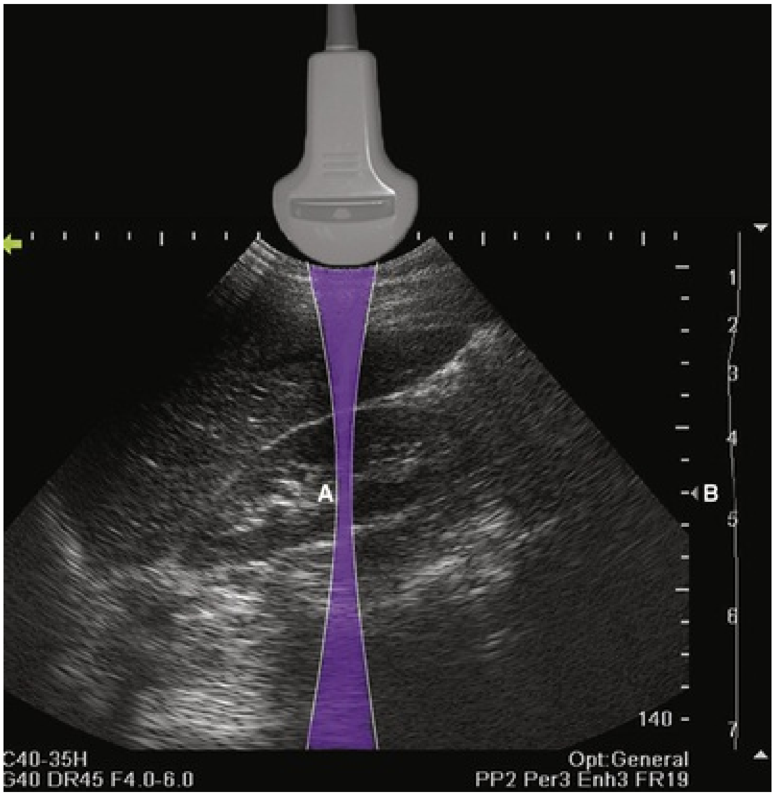

FIG. 4.6 The shape of the ultrasound beam is simulated in this drawing *(purple).* The focal zone *(A)* is located to produce the best lateral resolution of the medial renal cortex. The location of the focal zone is designated by the caret *(B).* The location of the focal zone can be adjusted by the operator.

The velocity with which a sound wave travels through tissue is a product of its frequency and wavelength (Fig. 4.7). The **average velocity of sound in human tissues is 1540 meters per second.** Because the average velocity of sound in tissue is a constant, changes in frequency result in changes in wavelength.

$$v = f \times \lambda$$

$$\text{velocity} = \text{frequency} \times \text{wavelength}$$

FIG. 4.7 The relationship among velocity, frequency, and wavelength of sound waves in tissue. Wavelength and frequency vary in an inverse relationship.

The optimal ultrasound image requires trade-offs between resolution and depth of penetration. High-frequency transducers of 7 to 18 MHz may be used to image structures near the surface of the body (e.g., testis, pediatric kidney) with excellent resolution. Consequently, images of deeper structures acquired at lower frequencies have poorer axial resolution than images of more superficial structures obtained at higher frequencies.

Mechanisms of Attenuation

As sound waves transit tissues, energy is lost or attenuated. Mechanisms of attenuation include **reflection, scattering, interference, and absorption**. Reflection is the key physical phenomenon that allows for information to return to the transducer as mechanical energy. Reflection occurs when ultrasound waves strike an object, a surface, or a boundary (called an **interface**) between unlike tissues. The shape and size of the object and the angle at which the advancing wave strikes the object are critical determinants of the amount of energy reflected. The amount of energy reflected from an interface is also influenced by the **impedance** of the two tissues at the interface. Impedance is a property that is influenced by tissue stiffness and density. It is the difference in impedance that allows an appreciation of interfaces between different types of tissue (Table 4.1).

TABLE 4.1

Density and Impedance of Tissues Encountered During Urologic Ultrasound

	DENSITY (kg/m^3)	IMPEDANCE (kg/m^{2}s)
Air and other gases	1.2	0.0004
Fat tissue	952	1.38
Water and other clear liquids	1000	1.48
Kidney (average of soft tissue)	1060	1.63
Liver	1060	1.64
Muscle	1080	1.70

Bone and other calcified objects	1912	7.80

The impedance difference between perinephric fat and the kidney allows a sharp visual distinction at the interface. If the impedance difference between tissues is small (such as that between the liver and kidney), the interface between the tissues will be more difficult to see (Fig. 4.8A). If impedance differences are large, there will be significant reflection of the sound wave producing an acoustical shadow distal to the interface (Fig. 4.8B).

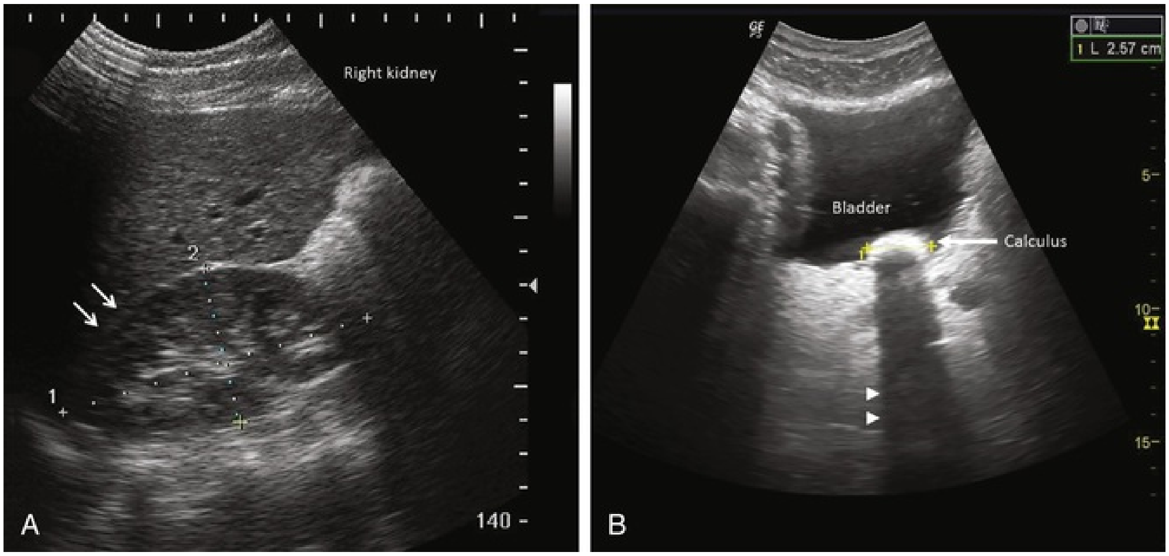

FIG. 4.8 (A) In this sagittal view of the right kidney, the paucity of perinephric fat and the small impedance difference make it difficult to distinguish the interface between the kidney and the liver *(arrows).* (B) The large impedance difference at the interface between urine and this bladder stone *(arrow)* results in significant reflection and attenuation of the sound wave. An acoustic shadow is seen distal to the stone *(arrowheads).*

Scattering occurs when sound waves strike a small or irregular object. The resulting spheric wave overlaps those of surrounding scattering objects (Fig. 4.9).

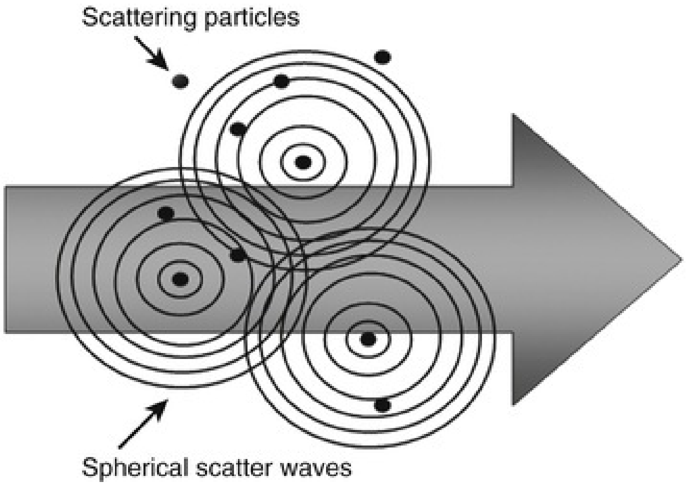

FIG. 4.9 Scattering is a phenomenon that occurs when sound waves strike small objects. The resulting pattern of energy dispersal often results in interference.

When interacting sound waves are in phase or out of phase, their amplitude will be enhanced or diminished. This **pattern of interference** is partially responsible for the echo architecture or texture of organs. One pattern of interference, commonly called **"speckling"** (Fig. 4.10), is seen in organs with fine, internal histology (i.e., reflectors) such as the testis.

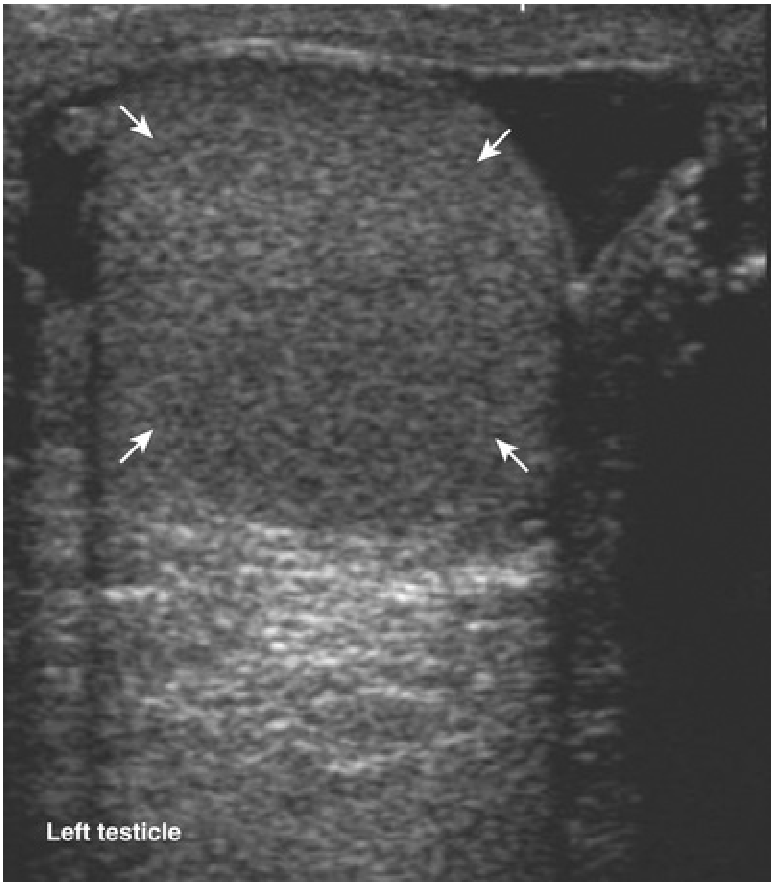

FIG. 4.10 Fine internal echogenicity called "speckle" is caused by scattering of sound waves and the resultant pattern of interference. Note the resulting finely granular, homogenous echogenicity *(arrows)* of the testicular parenchyma.

Absorption occurs when the mechanical energy of the ultrasound waves is converted to heat. Absorption is directly proportional to frequency. Therefore the higher the frequency of the incident wave is, the greater will be the absorption of energy and the more tissue heating that will result. Higher-frequency waves are more rapidly attenuated and therefore have a limited depth of penetration (Fig. 4.11).

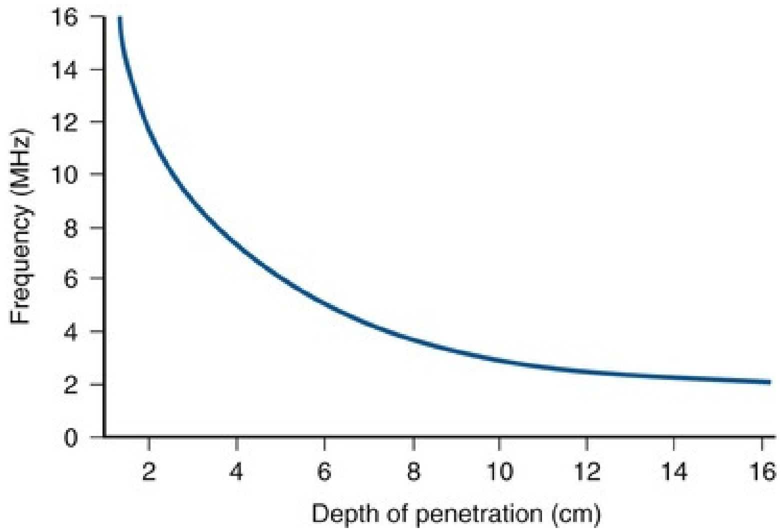

FIG. 4.11 The relationship between frequency and tissue penetration. High-frequency sound waves are rapidly attenuated and are unable to penetrate deeply. Conversely, low-frequency waves are less attenuated and able to penetrate deeply to internal structures.

Artifacts

The interaction of ultrasound waves with tissues may produce images that do not reflect the true underlying anatomy. These misrepresentations are called "artifacts." Artifacts may be misleading but, if recognized, may also assist in diagnosis. **Acoustic shadowing** occurs when there is significant attenuation or reflection of sound waves at a tissue interface. Echo information posterior to the interface may be obscured or lost. An anechoic or hypoechoic "shadow" is produced. Under these conditions, three-dimensional (3D) objects such as stones may appear as crescentic objects, making it difficult to obtain accurate measurements (Fig. 4.12). Important pathology posterior to such an interface may be missed. This problem may often be overcome or mitigated by changing the angle of insonation, changing the frequency of the transducer, or changing the focal zone of the transducer.

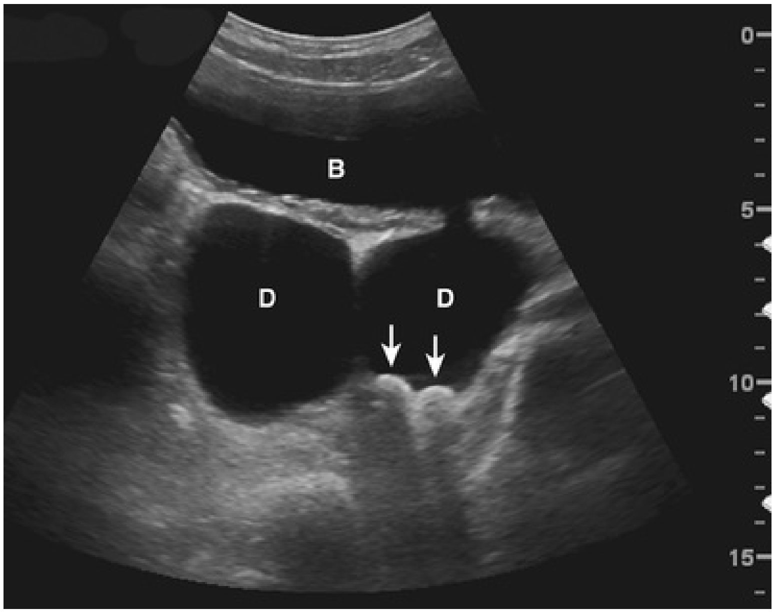

FIG. 4.12 In this transverse view of the urinary bladder *(B),* there are two large bladder diverticula *(D).* Two stones *(arrows)* strongly reflect and attenuate the incident sound wave, producing an acoustic shadow. Note that the stones appear crescentic even though they are ovoid.

Increased through transmission is observed when sound waves are less attenuated while passing through a given structure or tissue than by the surrounding tissues. For example, when a simple cyst of the kidney is imaged, sound waves passing through the cyst are less attenuated than those passing through the surrounding renal cortex and renal sinus. When the waves transiting the cyst strike the back wall of the cyst and posterior renal tissue, the waves are more energetic on arrival to these tissues. The reflected sound waves are also more energetic and less attenuated as they return to the transducer. The result is that tissue posterior to the cyst appears hyperechoic compared with the surrounding renal tissue, even though the tissues are histologically identical (Fig. 4.13). The effect of this artifact can be mitigated by changing the angle of insonation or adjusting the time-gain compensation (TGC) settings.

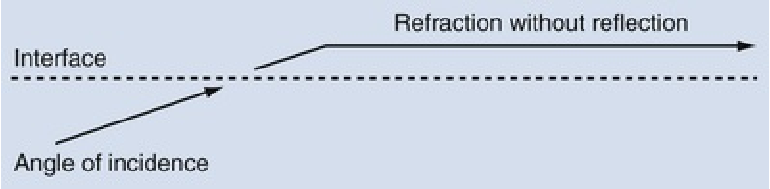
FIG. 4.13 Increased through transmission (also called *distal enhancement*) is demonstrated in this longitudinal view of the left kidney. The tissue distal to the cyst appears hyperechoic (indicated by *arrows*) compared with adjacent tissue.

An **edging artifact** occurs when sound waves strike a curved surface or interface at an incident angle, resulting in refraction of the wave along the plane of the interface (Fig. 4.14).



Refraction without reflection
Interface
Angle of incidence

FIG. 4.14 When sound waves strike a surface or interface at a “critical angle,” the wave is refracted without significant reflection.

An incident wave at this angle (the critical angle) will not be directly reflected to the transducer, resulting in a hypoechoic “shadow.” This artifact is commonly seen in testicular ultrasonography and transrectal ultrasonography (Fig. 4.15). It can be overcome by changing the angle of insonation.

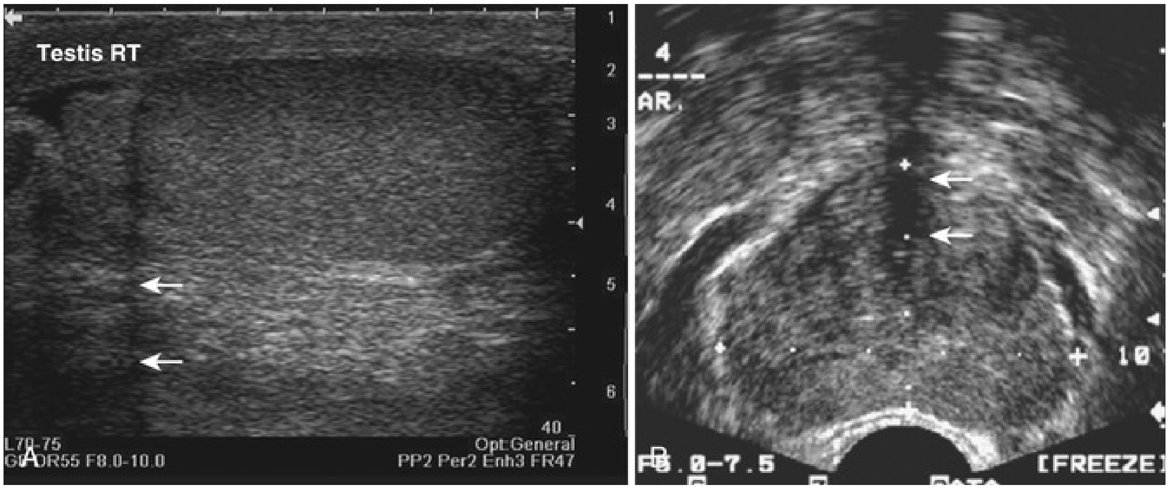


FIG. 4.15 (A) The curved surface of the tunica albuginea of the upper pole of testis creates a critical angle edging artifact *(arrows).* (B) The rounded surfaces of the lateral lobes of the prostate as they meet in the prostatic urethra create an edging artifact *(arrows)* in this transverse image of the prostate.

A **reverberation artifact** results when there are large differences in impedance between two adjacent tissues or surfaces with a strong reflection of the incident wave. The ultrasound wave bounces back and forth (reverberates) between the reflective interfaces. With the second transit of the sound wave, the ultrasound equipment interprets a second object that is twice as far away as the first. There is ongoing attenuation of the sound wave with each successive reverberation, resulting in a slightly less echoic image displayed on the screen. Therefore images are produced, spaced at equal intervals from the transducer but progressively less echoic (Fig. 4.16).

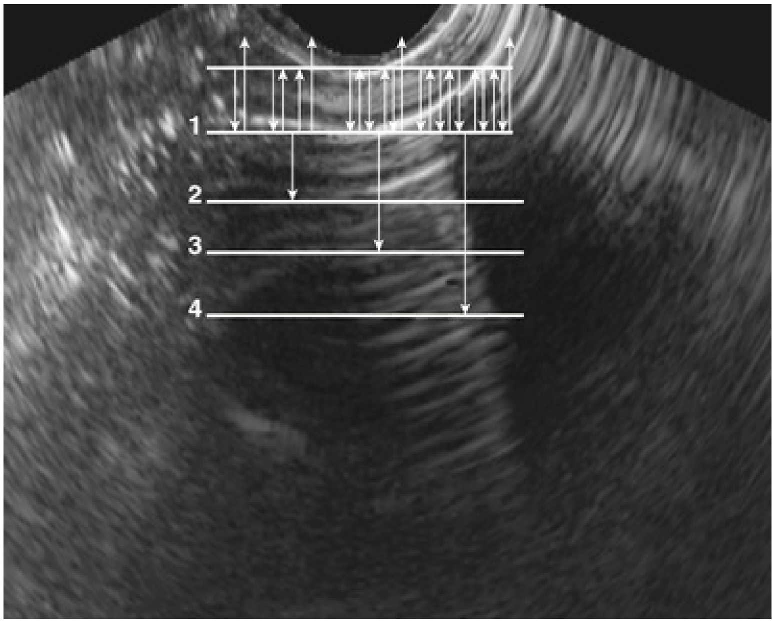

FIG. 4.16 Reverberation artifact. The strongly reflective interface is projected with decreasing amplitude as the incident sound wave makes multiple round trips.

The reverberation artifact can also be seen in cases in which the incident sound wave strikes a series of smaller reflective objects (such as the gas-fluid mixture in the small bowel), which results in multiple reflected sound waves of various angles and intensity (Fig. 4.17). The resultant echo pattern is a collection of hyperechoic artefactual reflections distal to the structure with progressive attenuation of the sound wave.

FIG. 4.17 When ultrasound strikes a structure such as bowel, which contains gas bubbles (A), the resultant reverberation artifact has a characteristic appearance sometimes called a “comet tail.” (B) A comet tail artifact produced by bowel gas *(arrows)* obscures the lower pole of the kidney.

Modes of Ultrasound

Gray-Scale Ultrasound

Gray-scale B-mode ultrasonography is the most commonly employed mode of ultrasound. This pulsed-wave technique produces real-time two-dimensional (2D) images consisting of shades of gray. The generation of this image involves assigning a pixel brightness to the amplitude of the returning sound waves received by the transducer. The position of the pixel is determined by the duration of the round trip of the sound wave. Individual lines of data are displayed sequentially on the monitor to produce a continuous or real-time image. Evaluation of gray-scale imaging requires the ability to recognize normal patterns of echogenicity from anatomic structures. Variations from these expected patterns of echogenicity indicate disorders of anatomy or physiology.

Doppler Ultrasound

The Doppler ultrasound mode depends on the physical principle of frequency shift when sound waves strike a moving object. The basic principle of Doppler ultrasound is that sound waves of a certain frequency will be shifted or changed on the basis of the direction and velocity of the moving object as well as the angle of insonation. This phenomenon allows for the characterization of motion, most commonly the motion of blood through vessels, but it may also be useful for detecting the flow of urine.

Color Doppler ultrasonography allows for evaluation of the velocity and direction of motion. A color map may be applied to direction with the most common assignation of the color blue to motion away from the transducer and red to motion toward the transducer. The velocity of motion is designated by the intensity of the color; thus the brighter the color, the greater the velocity. Color Doppler may be used to evaluate the presence or absence of blood flow in the kidney, testes, penis, and prostate. It also may be useful in the detection of ureteral “jets” of urine emerging from the ureteral orifices.

Color flow with spectral display is a mode that allows the interrogation of particular areas within an ultrasound field for flow and displays the flow as a continuous wave form. This mode is commonly used to evaluate the pattern and velocity of blood flow in the intrarenal or penile vasculature. The waveform provides information about peripheral vascular resistance in the tissues. The most commonly used index of these velocities is the resistive index. The **resistive index** is a ratio of peak systolic velocity minus the end-diastolic velocity over the peak systolic velocity. This index is helpful in characterizing a number of clinical conditions, including renal artery stenosis, ureteral obstruction, and penile arterial insufficiency.

Power Doppler ultrasonography is a mode that assigns the amplitude of frequency change to a color map. This does not permit evaluation of velocity or direction of flow but is less affected by back-scattered waves and therefore a more sensitive mode for detecting blood flow. Power Doppler is less angle dependent than color Doppler and is three to five times as sensitive as color Doppler ultrasound for detecting flow. Therefore it may be useful for evaluating testicular torsion.

Harmonic Scanning

Harmonic scanning makes use of aberrations related to the nonlinear propagation of sound waves within tissue. These asymmetrically propagated waves generate fewer harmonics, but those that are generated have greater amplitudes. Because these harmonics are not subject to scattering at the frequency associated with the incident wave, there is less noise associated with the signal. Concentrating on the harmonic frequencies produced within the body and reflected to the transducer allows production of an image with less artifact and greater resolution (Fig. 4.18).

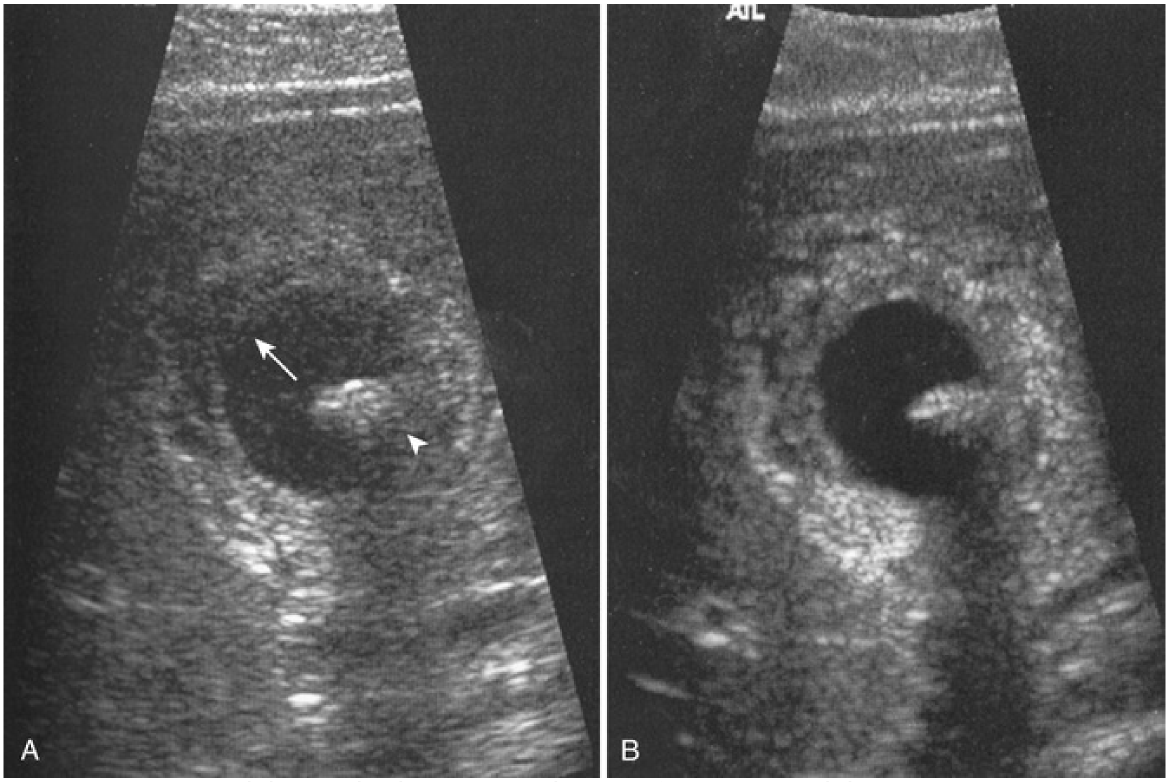

FIG. 4.18 (A) Standard gray-scale image of a cyst containing a mural nodule *(arrowhead).* Note the artifactual echogenicity within the cyst *(arrow).* (B) The same structure on harmonic scanning is more clearly seen. There is less artifact within and distal to the cyst. (From Merritt CRB: Physics of ultrasound. In Wilson S, Rumack C, eds: *Diagnostic ultrasound,* ed 3, St. Louis, 2005, Elsevier.)

Spatial Compounding

Spatial compounding is a scanning mode whereby the direction of insonation is electronically altered and a composite image is generated. This technique reduces the amount of artifact and noise, producing a scan of better clarity.

Sonoelastography

The ability to access pathology by palpation has long been a key part of a physician's physical examination. Hard lesions are often a sign of pathology. Sonoelastography (tissue elasticity imaging) is an ultrasound modality that adds the ability to evaluate the elasticity (compressibility and displacement) of biologic tissues. Essentially, it gives a representation, using color, of the softness or hardness of the tissue of interest. But how do we use ultrasound to "palpate" an organ? To do so requires a compressing mechanical wave to be produced in the tissue of interest. Presently, there are two ways to produce this mechanical wave: real-time elastography (RTE) and shear wave elastography (SWE).

In RTE, as in standard diagnostic, an external, nonquantifiable mechanically produced compression wave travels in tissue (1540 m/s). These waves successively compress tissue layers, producing backscattered reflected waves that are received and processed by the ultrasound equipment producing an image. Because the stress producing the mechanical compression wave cannot be directly measured, only a relative elasticity can be determined.

With RTE (Fig. 4.19) deformation is induced by manually pressing on the anatomy with the transducer and is measured using ultrasound. RTE is a qualitative technique and highly user dependent. Because of the requirement of manual displacement, RTE cannot measure absolute tissue stiffness as currently employed. Its major benefits are that it has a high spatial resolution, is a real-time measurement, and does not require any modifications to conventional ultrasound hardware. Spatial resolution is the ability to distinguish two separate objects that are close together and encompasses axial resolution and lateral resolution as defined previously.

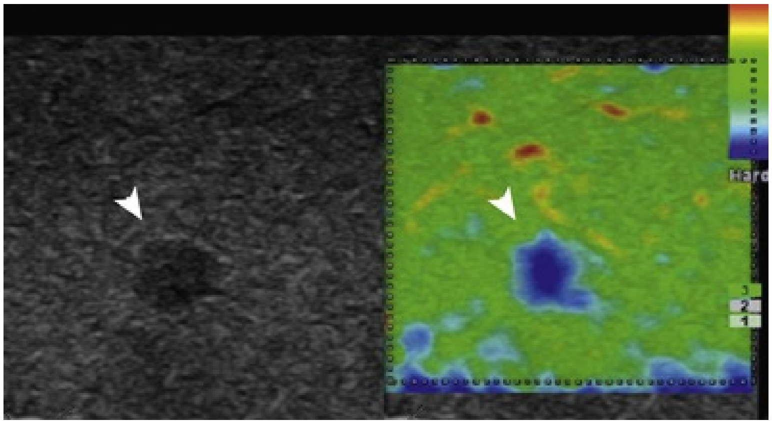

FIG. 4.19 Real-time elastography. A 4-mm hypoechoic nodule *(arrowhead, left panel)* was found with Doppler ultrasound with vascular flow internally. Real-time sonoelastography suggested a hard nodule (with this equipment blue is hard, not soft). Close follow-up with ultrasound every 3 months found no increase in size of the nodule. It was therefore considered “probably” benign. (From Goddi A et al: Real-time tissue elastography for testicular lesion assessment. *Eur Radiol* 22[4]:721–730, 2012.)

In SWE the shear wave produced can be measured precisely and travels more slowly (1 to 10 m/s). The shear wave is propagated by a tangential “sliding” force between tissue layers. The elasticity (E), density of the tissue (p, kg/m^2), and shear wave propagation speed (c) are directly related through the following equation:

$$E = 3pc^2$$

Therefore, by measuring the shear wave propagation speed, practitioners can directly determine the elasticity of the tissue.

With SWE (Figs. 4.20A and 4.20B), low-frequency (~100-Hz) pulses are rapidly transmitted into the tissue to induce a vibration in the tissue. Depending on the manufacturer's implementation, the vibrations can be induced in a single area or in a vertical plane by rapidly altering focal depth. Subsequently the observation of the propagation velocity of the resultant transient shear waves determines the viscoelastic properties of the tissues. Two typical limitations of generated shear waves are that (1) they are very weak, resulting in only a few millimeters of propagation and (2) detection of shear wave propagation requires very rapid acquisition speeds (pulse repetition frequency is >5000 Hz), which may limit the area of detection. However, some new-generation ultrasound systems have overcome these obstacles and allow large areas of interest to be displayed at near real-time imaging frame rates.

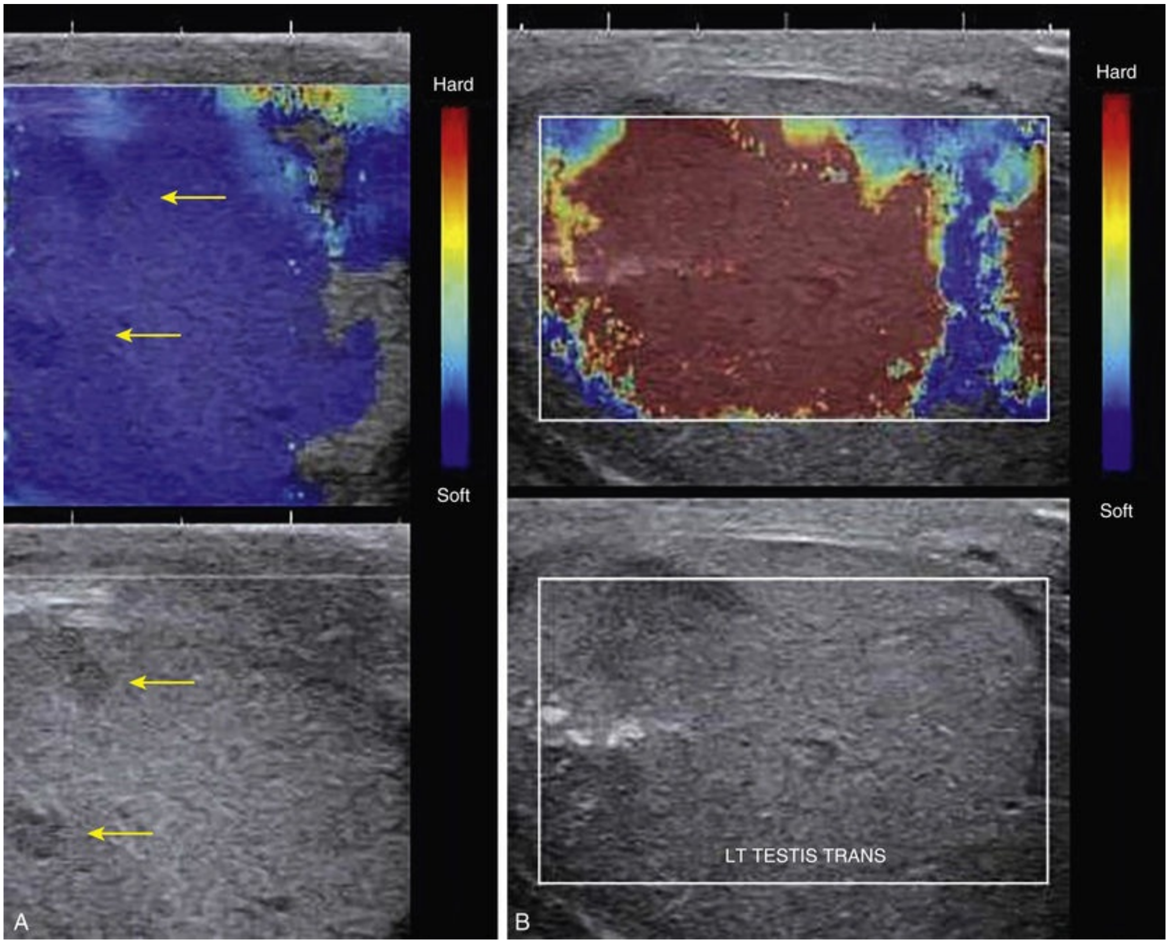

FIG. 4.20 Shear wave elastography. (A) Two small hypoechoic vascular lesion *(arrows, lower panel)* found with B-mode ultrasound is shown in the upper panel to be a soft *(blue)* lesion with shear wave elastography ultrasound. Biopsy confirmed a Sertoli cell nodule. (B) A larger lesion with heterogeneous echogenicity on B-mode ultrasound *(lower panel)* demonstrates diffuse "hardness" on shear wave elastography *(upper panel)*. Pathology demonstrated a nonseminomatous germ cell tumor.

Several approaches for elastography have been introduced. All of them have three common steps:

1. The sonographer manually compresses (in RTE) or the machine automatically generates (in SWE) a low-frequency vibration in tissue to induce stress.
2. The tissue is imaged with the goal of analyzing the resulting strain.
3. Parameters are defined related to tissue stiffness.

The principle of elastography is based on the concept that a given force applied to softer tissue results in a larger displacement than the same force applied to harder tissue. Measuring the tissue displacement induced by compression allows estimation of the tissue hardness and differentiation between benign (soft) from malignant (hard) lesions. This relationship between stress (s) and strain (e) is given by Young's modulus of elasticity (E):

$$E = s/e$$

E is larger in hard tissues and lower in soft tissues.

Visually, the elasticity of a tissue is represented by color spectrum. Be aware that the color given to hard lesions is determined by the manufacturer of the equipment and can be set by the user. Therefore, just as in using color Doppler, the user needs to look at the color bar (see Figs. 4.19 and 4.20) to know what color represents a “hard” and “soft” lesion.

Three-Dimensional Scanning

Three-dimensional (3D) scanning has been used extensively in obstetrics and gynecology but so far has limited application in urology. 3D scanning produces a composite of images (data set), which can then be manipulated to generate additional views of the anatomy in question (Fig. 4.21). 3D rendering may be important in procedural planning and precise volumetric assessments (Ghani et al., 2008a; Ghani et al., 2008b). 3D scanning may allow the recognition of some tissue patterns that would otherwise be inapparent on 2D scanning (Mitterberger et al., 2007b; Onik and Barzell, 2008).

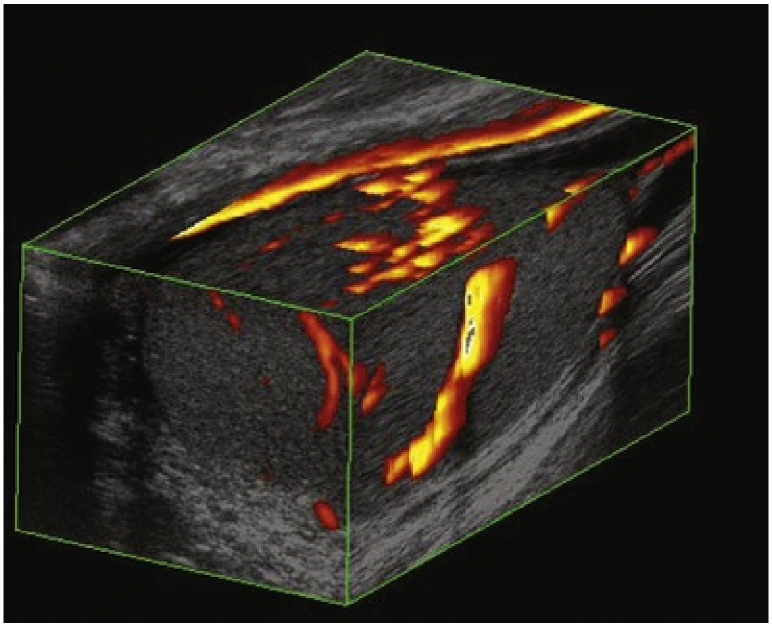

FIG. 4.21 A three-dimensional image of the testis demonstrating intratesticular blood flow on power Doppler. The image can be virtually rotated and manipulated to produce unique anatomic perspectives. (Used with permission by BK Medical.)

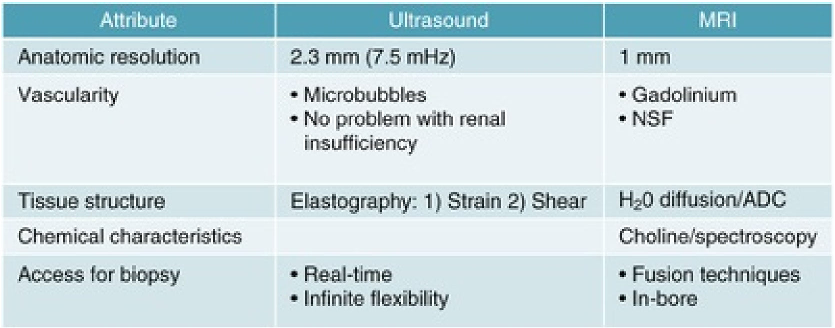
Multiparametric Ultrasound

The emergence of multiple modalities of ultrasound, including gray-scale, Doppler, elastography, contrast-enhancement, and computer-enhanced imaging, has given rise to the concept of multiparametric ultrasound (mpUS). Just as multiparametric MRI (mpMRI) offers excellent anatomic resolution with T2-weighted imaging, ultrastructural histology with water diffusion, and vascularity with contrast enhancement, mpUS is able to address all of those tissue properties in real time. mpUS is already used in transrectal ultrasound of the prostate and is finding many applications in nonprostate ultrasound (Fig. 4.22).



Attribute	Ultrasound	MRI
Anatomic resolution	2.3 mm (7.5 mHz)	1 mm
Vascularity	• Microbubbles • No problem with renal insufficiency	• Gadolinium • NSF
Tissue structure	Elastography: 1) Strain 2) Shear	H_20 diffusion/ADC
Chemical characteristics		Choline/spectroscopy
Access for biopsy	• Real-time • Infinite flexibility	• Fusion techniques • In-bore

FIG. 4.22 Multiparametric ultrasound is compared with MRI. *ADC,* Apparent diffusion coefficient; *SNF,* systemic nephrogenic fibrosis.

Contrast Agents in Ultrasound

Intravenous compounds that contain microbubbles have been used for enhancing the echogenicity of blood and tissue. The addition of targeting ligands attached to the microbubble allows the microbubble complex to selectively accumulate in diseased or abnormal tissues. Microbubbles are distributed in the vascular system and create strong echoes with harmonics when struck by sound waves. The bubbles are rapidly degraded by their interaction with the sound waves. Contrast agents may be useful in prostatic ultrasonography by enhancing the ability to recognize areas of increased vasculature. Several intravenous ultrasound contrast agents have been approved by the US Food and Drug Administration (FDA) as of this writing. They have a good safety profile and have found use in a number of urologic scanning situations (Auer et al., 2017; Mitterberger et al., 2007a; Wildeboer et al., 2017; Wink et al., 2008).

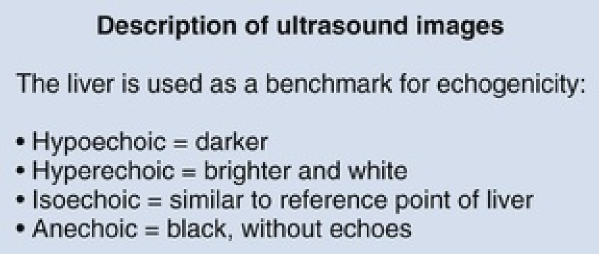
Documentation and Image Storage

Documentation is essential for ensuring high-quality patient care. Proper documentation includes the production a permanent record of the ultrasound examination and interpretation of the examination. This documentation is inclusive of the report and acquired images (American Institute of Ultrasound in Medicine, 2014). All documentation must be retrievable and comply with local, state, and federal requirements.

Report

The report should include specific identifiers, including the patient identification, the date of the examination, the measurement parameters, and a description of findings of the examination. Ideally the report should also include specifics of how the evaluation was performed, which would detail the transducer used, machine used, and settings employed. However, most of these should be on the recorded image that is also stored with the report. The report must be signed by the physician who performed the ultrasound examination, and prominently displayed at the top of the report should be the indications for performing the examination.

When urologists perform and interpret ultrasound studies, it is important that appropriate nomenclature be used to describe the objects imaged (Fig. 4.23). By convention, the liver is used as a benchmark for echogenicity. If a structure is hypoechoic, it means it is darker than the surrounding tissues. If it is hyperechoic, it means it is brighter than the surrounding tissues. Isoechoic means it is similar to the surrounding tissues. Structures that do not generate echoes are called *anechoic*. A simple cyst is an example of a structure with an anechoic interior. In general, a high water content causes tissue to appear hypoechoic. In general, a high fat content causes tissue to appear hyperechoic.



Description of ultrasound images

The liver is used as a benchmark for echogenicity:

- Hypoechoic = darker
- Hyperechoic = brighter and white
- Isoechoic = similar to reference point of liver
- Anechoic = black, without echoes

FIG. 4.23 The nomenclature for describing the appearance of ultrasound images.

Images

Images should include the patient identification, the date and time of each image, and clear image orientation. Measurements should also be clearly identified, and anatomy and any abnormalities should be labeled. The image should be interpretable by any appropriately trained sonographer and demonstrate a clear, unimpeded ultrasound image of the anatomy of interest. Images should always be attached to the report or be easily accessible from the report.

By convention, structures imaged by ultrasonography should be oriented so that the superior aspect of the structure is to the left as the image is viewed and the inferior aspect of the structure to the right. With paired structures, it is critically important to document right or left. It is useful to use equipment-generated icons to illustrate patient position and the orientation of insonation (Fig. 4.24).

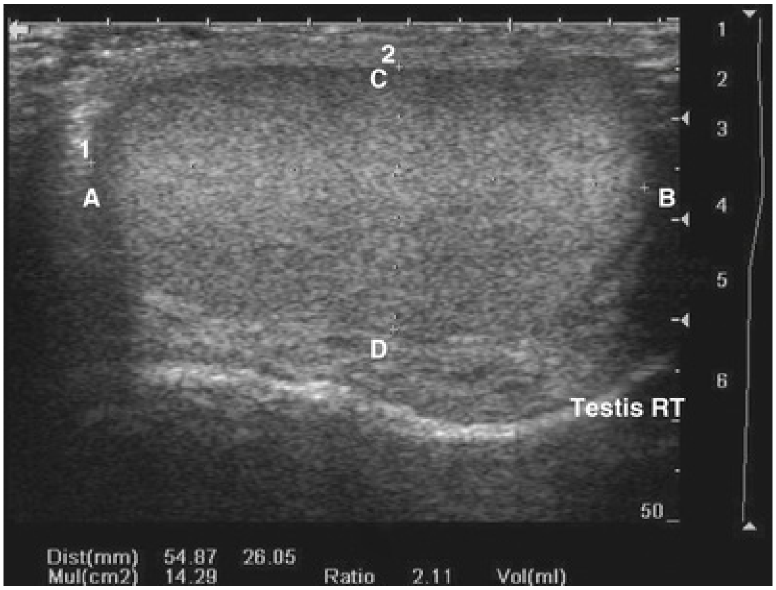


FIG. 4.24 In this sagittal image of the right testis, the superior pole of the testis *(A)* is to the left, and the inferior pole of the testis *(B)* is to the right. The anterior aspect of the testis *(C)* is at the top of the image and the posterior aspect *(D)* at the bottom. Without the label, there would be no way to distinguish the right from the left testis.

The appropriate number of images to be captured for documentation is the number necessary to document a systematic and complete examination and to document relevant pathology.

Report and Image Storage

The use of electronic medical records has made the documentation of ultrasound examinations somewhat easier. However, it has also created challenges in the archiving of images for easy reviewing. These images can occupy large portions of digital storage and, because they are part of the medical record and contain protected health information (PHI), must comply with local, state, and federal regulations. The widespread use of cloud storage has created an opportunity for many vendors as well as challenges regarding how to secure this information. Fortunately, there are many validated systems available for small and large practices that meet current regulatory requirements.

Patient Safety

Diagnostic ultrasonography transmits energy into the patient that has the potential to produce biologic effects. The two main categories of biologic effects are **mechanical effects** and **thermal effects.**

The mechanical effects of ultrasonography are torque and streaming. The mechanical effects of an acoustic field may produce a phenomenon called *cavitation.* **Cavitation** occurs when small gas-filled bubbles form and then collapse. These collapsing bubbles liberate a large amount of energy, which may cause damage to tissue in certain circumstances. Mechanical effects are most likely to be observed around gas-containing structures such as lung and bowel.

The thermal effects of ultrasonography are primarily the result of tissue heating resulting from the absorption of energy. The amount of tissue heating is influenced by several factors, including beam focusing, transducer frequency, exposure time, scanning mode, and tissue density.

To assist the sonographer in monitoring the bioeffects of ultrasound, the ultrasonography community has adopted the **output display standard (ODS).** Two values are typically displayed: the **mechanical index (MI)** and the **thermal index (TI).** These indices are calculated **estimates** of the potential for bioeffects of ultrasonography based on the mode of ultrasonography being used, frequency, power output, and time of insonation. The MI indicates the probability that cavitation will occur. For tissues not containing stabilized gas bodies (lung and intestine), the risk of cavitation is low as long as the MI is less than or equal to 0.7. For structures adjacent to lung or intestine, scanning time should be limited if the MI exceeds 0.4. The TI indicates the probability that tissue temperature within the sonographic field will be increased by 1°C. The precise consequences of tissue heating are not completely understood, but even tissue temperature elevations of up to 6°C are not likely to be dangerous unless exposure time exceeds 60 seconds. TI values should be less than 2 for most urologic ultrasound studies (Nelson et al., 2009). The MI and TI typically are displayed on the monitor during ultrasound examinations, and all practitioners should be familiar with the location. **These indices are not safety limits.**

In general, ultrasonography performed by urologists has a low risk for patient harm as long as standard protocols are followed (Rumack and Wilson, 2005). Although tissue heating may occur, there are no confirmed biologic effects of tissue heating in nonfetal scanning except when they are sustained for extended periods. Users should be aware that for soft tissues not known to contain gas bodies, there is no basis in present knowledge to suggest an adverse nonthermal bioeffect from current diagnostic instruments not exceeding the FDA output limits (Rumack and Wilson, 2005). Nevertheless, all urologists should endeavor to follow the principles of **ALARA,** which stands for **"As Low As Reasonably Achievable."** The ALARA principle is intended to limit the total energy imparted to the patient during an examination. This can be accomplished by (1) keeping power outputs low, (2) using appropriate scanning modes, (3) limiting examination times, (4) adjusting focus and frequency, and (5) using the cine function during documentation.

In summary, ultrasound scanning offers an excellent, cost-effective modality for diagnosing and treating urologic conditions. **The most important factor in ultrasound safety is the informed operator.** Urologists should endeavor to perform limited examinations using consistent technique for specific indications. Patient safety and equipment maintenance should be emphasized in all the environments where ultrasound technology is used.

Clinical Urologic Ultrasound

The use of ultrasonography in urology has expanded dramatically because of its profound utility in the clinic and operating room. In addition to being the mainstay of the diagnosis of prostatic disease, ultrasonography is increasingly being used by urologists in the clinical environment for initial diagnosis, interventional management, and longitudinal follow-up of urologic diseases.

Renal Ultrasound

Urologists, because of their intimate knowledge of surgical anatomy of the kidneys and retroperitoneum, are uniquely qualified to perform and interpret selected ultrasound examinations of the abdomen. These skills are relevant in the office and the operating room environment. Urologists generally perform abdominal ultrasonography for a specific clinical indication and less often for general screening of the abdominal contents. Therefore, in most clinical situations, a limited retroperitoneal examination is used in urologic practice.

Technique

The transducer normally used for renal ultrasonography is a curved array transducer of 3.5 to 5.0 MHz. Transducers of a higher frequency may be used for pediatric patients. For intraoperative and laparoscopic renal ultrasonography, a linear array transducer of 6 to 10 MHz is typically employed.

Scanning of the right kidney is performed with the patient supine. The kidney is located by beginning in the midclavicular line in the right upper quadrant. In the sagittal plane the transducer is moved laterally until the midsagittal plane of the kidney is imaged. Once the kidney has been imaged anteriorly and posteriorly in the sagittal plane, the probe is rotated 90 degrees counterclockwise. The midtransverse plane will demonstrate the renal hilum containing the renal vein. The kidney is scanned from the upper pole to the lower pole.

The technique and documentation for left renal ultrasonography is identical to that of the right side. However, the left kidney is slightly more cephalad than the right kidney. Bowel gas is more problematic on the left because of the position of the splenic flexure of the colon. Visualization of the left kidney often requires the patient to be turned into a lateral position. Ultrasound imaging of the left kidney lacks the liver as an acoustic window, and it is sometimes more difficult to image the left kidney in a true sagittal plane.

Indications

1. Assessment of renal and perirenal masses
2. Assessment of the dilated upper urinary tract
3. Assessment of flank pain during pregnancy
4. Evaluation of hematuria in patients who are not candidates for IVP, CT, or MRI because of renal insufficiency, contrast allergy, or physical impediment
5. Assessment of the effects of voiding on the upper urinary tract
6. Evaluation for and monitoring of urolithiasis
7. Intraoperative renal parenchyma and vascular imaging for ablation of renal masses
8. Percutaneous access to the renal collecting system
9. Guidance for transcutaneous renal biopsies, cyst aspiration, or ablation of renal masses
10. Postoperative evaluation of patients after renal and ureteral surgery
11. Postoperative evaluation of renal transplant patients

Normal Findings

It is helpful during scanning of the kidney to understand its anatomic position within the retroperitoneum. This assists in identifying the midsagittal plane, which serves as a reference point for a complete examination (Fig. 4.25).

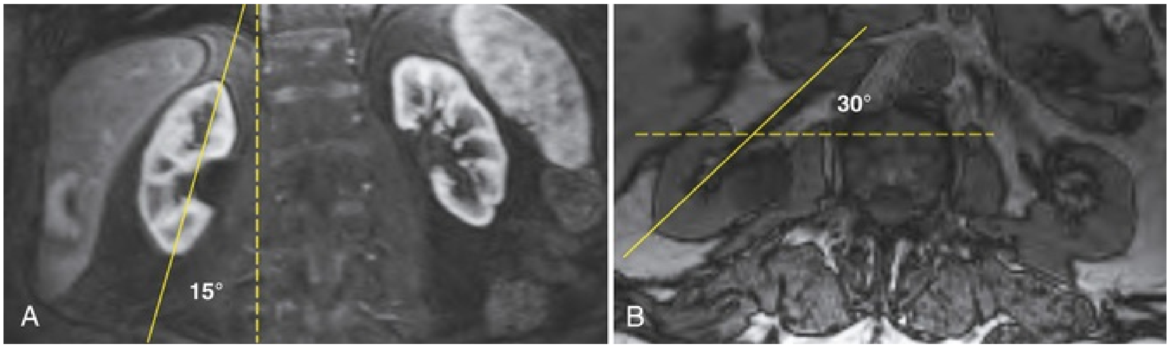

FIG. 4.25 The lower pole of the kidney is displaced 15 degrees laterally compared with the upper pole (A). The kidney is rotated 30 degrees

posterior to the true coronal plane (B). The lower pole of the kidney is slightly anterior compared with the upper pole.

The adult right kidney in the sagittal view demonstrates a cortex that is usually hypoechoic with respect to the liver. The central band of echoes in the kidney is a hyperechoic area that contains the renal hilar adipose tissue, blood vessels, and collecting system. Acoustic shadowing from ribs overlying the inferior pole can be eliminated by moving the probe to a more lateral position or into the intercostal space. By having the patient take a deep breath, the kidney can be moved inferiorly to assist complete imaging (Fig. 4.26).

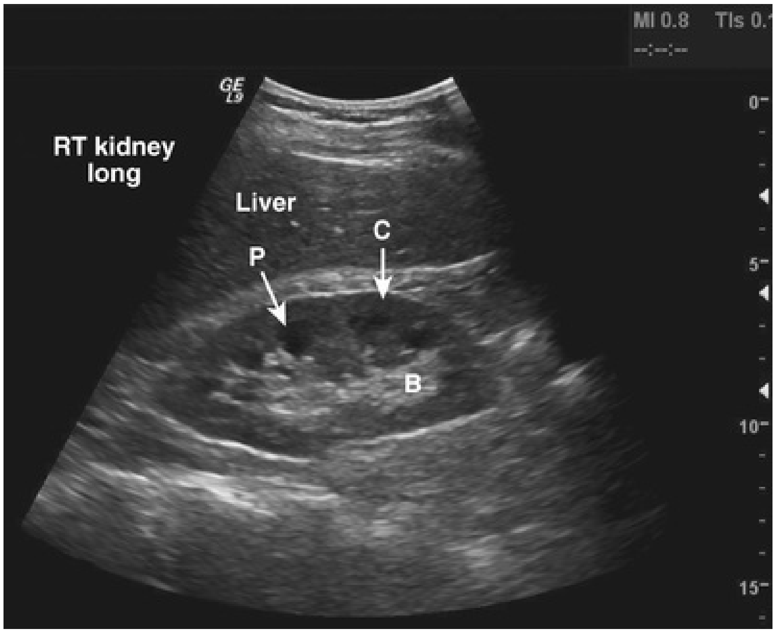

FIG. 4.26 Midsagittal plane of the kidney. Note the relative hypoechogenicity of the renal pyramids *(P)* compared with the cortex *(C).* The central band of echoes *(B)* is hyperechoic compared with the cortex. The midsagittal plane will have the greatest length measurement pole to pole. A perfectly sagittal plane will result in a horizontal long axis of the kidney.

The echogenicity of the kidney varies with age. The renal cortex of an infant is relatively hyperechoic compared with that of an adult. In addition, there is a smaller and less apparent central band of echoes in the infant. In the adult, the echogenicity of the renal cortex is usually hypoechoic with respect to the liver (Emamian et al., 2013). In patients with chronic medical renal diseases the renal cortex is often thinned and isoechoic or hyperechoic with respect to the liver (O'Neill, 2001).

Renal size changes over the lifetime of an individual. Nomograms for pediatric renal size should be consulted. These are based on age, height, and weight of the patient. The average adult kidney measures 10 to 12 cm in length and 4 to 5 cm in width. Measurements of renal volume may be appropriate in cases of severe renal impairment. Renal measurements should be obtained in the midsagittal plane and midtransverse plane. Measurements taken in other than the midsagittal plane and midtransverse may be spuriously low. The thickness of the parenchyma is the average distance between the renal capsule and the central band of echoes. The precise location for making this measurement is somewhat subjective. The midlateral renal parenchyma in the sagittal view is a common choice for obtaining this measurement (Fig. 4.27). Although there is no universal standard, the renal cortical thickness should be greater than 7 mm (Roger et al., 1994), and the renal parenchymal thickness should be greater than 15 mm in adults (Emamian et al., 2013).

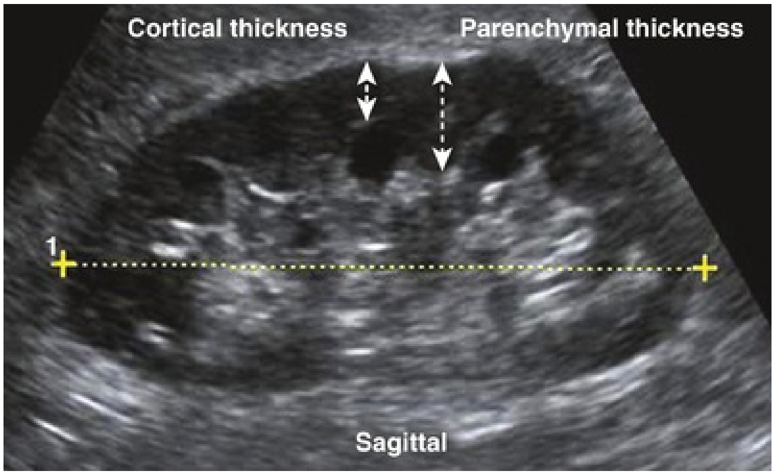

FIG. 4.27 The distinction between renal cortical thickness and renal parenchymal thickness is that the renal parenchyma is measured from the central band of echoes to the renal capsule. The renal cortex is measured from the outer margin of the medullary pyramid to the renal capsule.

Doppler ultrasound may be helpful in evaluating the renal artery and renal vein and assessing the vascular resistance in the kidney. Doppler modes may also be useful in evaluating neovascularity associated with renal tumors and in correctly characterizing hypoechoic structures in the renal pelvis such as a parapelvic cyst, the renal vein, or the dilated collecting system.

Procedural Applications

Percutaneous renal biopsy as an office procedure has been used by several groups for the past two decades and found to be a safe and effective procedure (Christensen et al., 1995; Fraser and Fairley, 1995; Hergesell, 1998). In a series of 131 ultrasound-guided biopsies by Christensen et al. (1995), complication occurred in 21% of patients with 18% considered minor and 3% major. In their series, increasing the number of biopsy passes did not increase the complication rate, but severe hypertension did. Fraser and Fairley (1995) compared 118 outpatient ultrasound-guided biopsies with 232 inpatient procedures and found no difference in complication rate. Hergesell et al. (1998) reviewed their series of 1090 percutaneous biopsies performed with local anesthesia and ultrasound guidance. They had only one case requiring interventional radiology for persistent blood loss, 2.2% with minor hematoma conservatively treated (25/1090), and self-limited macrohematuria in 0.8% (9/1090). They did note in a subset of their population evaluated by Doppler ultrasound hemodynamically irrelevant AV fistula in 9% (48/533). Sufficient tissue was obtained in 98.8%.

More recently Al-Hweish (Al-Hweish and Abdul-Rehaman, 2007) followed two groups. Group I (N = 22) had a 24-hour hospital admission after the biopsy, and group II (N = 22) was observed for 6 hours after the biopsy and then discharged. A small perinephric hematoma as observed in a single patient in group II and resolved spontaneously. Gross hematuria (13.6% and 9.1%, respectively) was the only significant complication they observed and occurred in all cases within 6 hours.

Safety and efficacy has also been found for pediatric (Davis et al., 1998; Hussain et al., 2003; Kamitsuji et al., 1999) and elderly patients (Kohli et al., 2006; Moutzouris et al., 2009; Stratta et al., 2007).

Limitations

Some patients are not favorable candidates for renal ultrasonography. Obesity, intestinal gas, and physical deformity may be impediments to complete renal evaluation. Renal ultrasonography has poor sensitivity for renal masses less than 2 cm (Warshauer, McCarthy, and Street, 1988). There is a lack of specificity for renal tumor type except for angiomyolipoma. Angiomyolipoma has characteristics that are distinctive on ultrasonography (highly echoic), but some small renal cell carcinomas have been shown to be indistinguishable from angiomyolipoma by ultrasound criteria (Forman, Middleton, and Melson, 1993; Yamashita, Takahashi, and Watanabe, 1992).

Transabdominal Pelvic Ultrasound

Transabdominal pelvic ultrasonography is a tremendously versatile tool for the urologist. It is a noninvasive method for evaluating the lower urinary tract and prostate in men and the bladder in women. A curved array transducer of 3.5 to 5 MHz is most commonly employed to perform transabdominal ultrasonography. In pediatric patients, a higher-frequency transducer may be used. For determining only a residual urine or bladder volume, an automated bladder scanner is often employed.

Technique

Bladder ultrasonography is most commonly performed with the patient supine and the sonographer on the patient's right side. The scan should be performed in a warm room and the patient draped to provide for comfort and privacy. If necessary, a roll may be placed beneath the patient's hips. Scanning technique depends on the circumstances and the reason for the examination but in general should be performed with a moderately full bladder. The bladder should be scanned in a sagittal and transverse manner, angling the probe into the pelvis so that the bladder can be visualized beneath the pubic bone. Although the prostate cannot be imaged with the same resolution achieved during transrectal scanning, the size and morphology of the prostate can be demonstrated. Although transabdominal scanning is the most common means of evaluating the bladder, the bladder may also be assessed via a transvaginal and transrectal approach. These approaches are useful in patients who are obese or who are not suitable candidates for transabdominal scanning.

Indications

1. Measurement of bladder volume or postvoid residual urine
2. Assessment of prostate size and morphology
3. Demonstration of secondary signs of bladder outlet obstruction
4. Evaluation of bladder wall configuration and thickness
5. Evaluation of hematuria of lower urinary tract origin
6. Detection of ureteroceles
7. Assessment for ureteral obstruction
8. Detection of perivesical fluid collections
9. Evaluation of clot retention

10. Confirmation of catheter position
11. Removal of retained catheter
12. Guidance of suprapubic tube placement
13. Establishment of bladder volume before and after flow rate determination

Normal Findings

Transabdominal pelvic ultrasonography should include evaluation of the lumen of the bladder, as well as bladder wall configuration and thickness. The presence of specific lesions such as stones or tumors should be documented. The structures immediately surrounding the bladder may also be evaluated including the distal ureters, the prostate in men, and the uterus and ovaries in women (Fig. 4.28). The emergence of urine from the ureteral orifices (ureteral jets) can be demonstrated. The clinical value of demonstrating ureteral jets has been questioned. Up to 10 minutes of continuous observation may be required to verify the absence of a ureteral jet (Fig. 4.29) (Delair and Kurzrock, 2006).

FIG. 4.28 (A) Transverse view of the bladder *(BL)* in this female patient demonstrates the uterus *(U)*. (B) Sagittal view of the bladder shows the uterus posterior to the bladder.

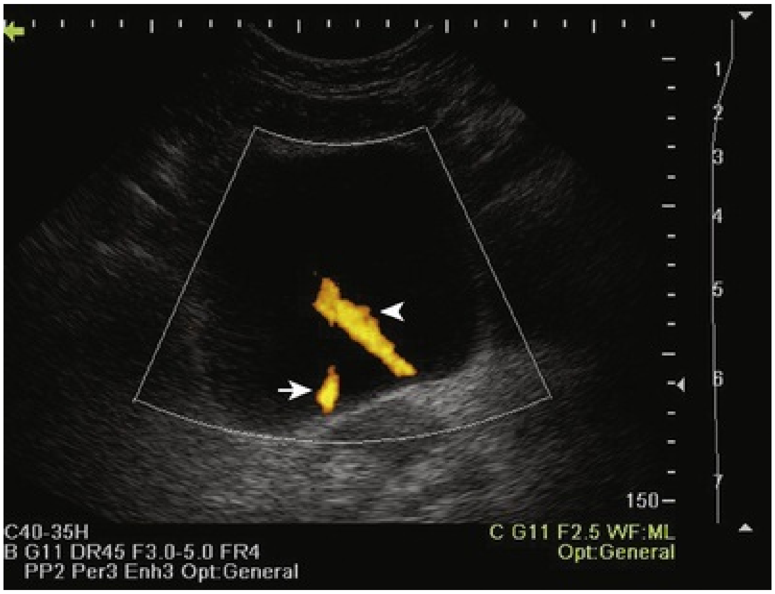

FIG. 4.29 In this transverse view of the bladder, ureteral "jets" emerging from the left *(arrow)* and right *(arrowhead)* ureteral orifices are demonstrated by power Doppler.

Bladder volume can be calculated manually by obtaining measurements in the midtransverse and midsagittal planes (Fig. 4.30). Numerous studies have shown that for bladder volumes between 100 and 500 mL, such calculated volumes are within 10% to 20% of the actual bladder volume (Ghani et al., 2008b; Park, Ku, and Oh, 2011; Simforoosh et al., 1997). Measuring bladder wall thickness may assist the clinician in understanding the degree of bladder outlet obstruction (Fig. 4.31). Bladder wall thickness varies depending on the volume of urine in the bladder and on which part of the bladder wall is measured. It has been shown that measuring bladder wall thickness may predict bladder outlet obstruction with greater accuracy than free uroflowmetry, postvoid residual urine, and prostate volume (Oelke et al., 2007).

FIG. 4.31 Bladder wall thickness may provide information about bladder outlet obstruction. In this sagittal view, bladder wall thickness is measured posteriorly *(arrow)* near the midline. Note the trabeculation of the relatively

hyperechoic bladder wall.

Transabdominal prostatic ultrasonography requires angling the probe beneath the pubic bone. In the transverse plane the transducer is fanned inferiorly until the largest transverse diameter of the prostate is identified. Measurements of the transverse width and height are obtained (Fig. 4.32A). The transducer is then rotated 90 degrees clockwise to produce a true sagittal image of the prostate. The transducer is fanned until the midline is identified. This is recognized by a V-shaped indentation at the bladder neck (Fig. 4.32B). Depending on the degree of prostatic hypertrophy and the presence or absence of a middle lobe, this “V” may be more or less apparent and more or less anterior or posterior in its position. A sagittal measurement is made from the bladder neck to the apex of the prostate. The apex of the prostate may be identified by using the hypoechoic urethra as a guide.

FIG. 4.32 (A) Transabdominal ultrasound is extremely useful for measuring prostatic volume and evaluating prostatic morphology. The volume of the prostate can be calculated using this formula: prostate volume (mL) = width (cm) × height (cm) × length (cm) × 0.523. (B) In this midsagittal view of the prostate, the bladder neck is identified as a V-shaped indentation *(arrow)*. Note the characteristically hyperechoic trigone *(arrowhead).*

The degree of protrusion of the prostate into the bladder may have some predictive value for bladder outlet obstruction. It has been shown that intravesical prostatic protrusion correlates relatively well with formal urodynamic evaluation of bladder outlet obstruction (Chia et al., 2003; Keqin et al., 2007). The measurement is obtained by drawing a line corresponding to the bladder base on sagittal scan and measuring the perpendicular distance from the bladder base to the greatest protrusion of the prostate into the bladder (Fig. 4.33).

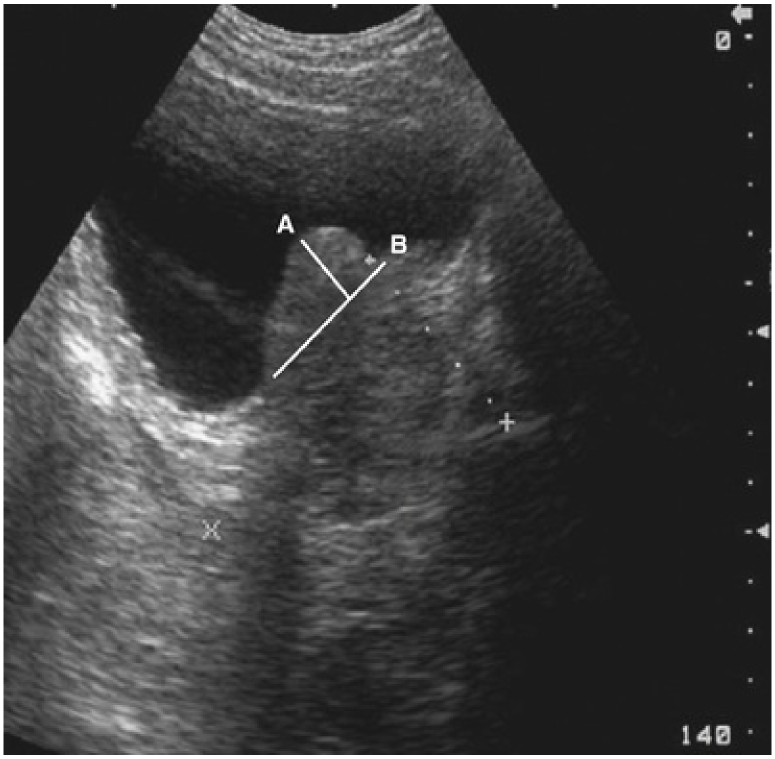

FIG. 4.33 In this sagittal view of the prostate, the middle lobe extends into the bladder *(A)*. The bladder base is defined by *line B*. The length of *line A* is the intravesical prostatic protrusion (IPP).

Transabdominal ultrasonography of the prostate is useful in characterizing prostatic urethral length, the size and configuration of the middle lobe of the prostate, and some secondary information about the physiology of bladder outlet obstruction. This information is valuable in treatment planning for bladder outlet obstruction.

Procedural Applications

Transabdominal ultrasound-guided percutaneous bladder aspiration with or without catheter placement has been successfully used in neonates, children, and adults (Gochman et al., 1991; Wilson and Johnson, 2003). It has also been employed for treatment of bladder stones (Ikari et al., 1993; Sofer et al., 2004). Ultrasound-guided aspiration has also been used for peritoneal drainage after bladder perforation (Manikandan et al., 2003).

Limitations

Transabdominal pelvic ultrasonography yields limited information in patients with an empty bladder. The ability to identify distal ureteral obstruction, bladder stones, and bladder tumors requires a full bladder. Although prostatic morphology and volume can be assessed with an empty bladder, it is much easier when the bladder is full. Pelvic structures may be difficult to evaluate in patients with a protuberant abdomen or panniculus. **Automated measurement of bladder volume or residual urine, although using ultrasonography, is not an imaging study.** Lack of imaging confirmation can lead to inaccurate residual urine determinations in patients with obesity, clot retention, ascites, bladder diverticulum, or perivesical fluid collection (e.g., urinoma, lymphocele).

Ultrasonography of the Scrotum

No aspect of urologic care is better suited to the use of ultrasonography than evaluation of the scrotum. Urologists have a surgical understanding of the anatomy and extensive experience with the diagnosis and treatment of disorders that affect the scrotum. Because the scrotum and its contents are superficial, high-frequency transducers may be employed to yield excellent and detailed anatomic and physiologic information. Imaging information can be correlated with findings on direct physical examination.

Technique

Sound technique is critical to performing adequate ultrasonography of the scrotum. In general, the examination should be carried out in a quiet room that is adequately warm for patient comfort. The patient should be supine with the scrotum supported on a towel or on the anterior thighs. The patient should be draped in such a way as to hold the penis out of the way and to ensure patient privacy. Copious amounts of conducting gel should be used to provide a good interface between the transducer and the scrotal skin because air trapping by scrotal hair results in unwanted artifacts. Complete but gentle contact between skin and transducer is essential because excessive pressure results in movement of testis or compression of the testis. Compression may change echogenicity and obscure fine anatomic detail. In addition, compression may significantly alter volume measurements.

Scrotal ultrasonography is performed with a high-frequency linear array transducer, generally in the range of 7 to 18 MHz. Transducers may be 4 to 7.5 cm in width. Some sonographers prefer the maneuverability of a 4-cm transducer, whereas others prefer the longer 7.5-cm transducer for its ability to simultaneously image the entire testis in the sagittal plane. Imaging should be done in a systematic fashion and should include sagittal and transverse views of the testis. The sagittal view should proceed from the midline medially and then laterally and from the midtransverse section of the testis to the upper pole and the lower pole of the testis. In addition to the testis, the epididymis and entire scrotal contents should be imaged.

Indications

1. Assessment of scrotal and testicular mass
2. Assessment of scrotal and testicular pain
3. Evaluation of scrotal trauma
4. Evaluation of infertility
5. Follow-up after scrotal surgery
6. Evaluation of the empty or abnormal scrotum

Normal Findings

It is important to document the size and, if appropriate, the volume of the testes. The echo architecture of the testis should be described (Fig. 4.34). It is important to compare the testes for echogenicity because some infiltrative processes may result in diffuse changes in a testis that would be noticed only when that testis is compared with its contralateral mate (Fig. 4.35). For example, lymphomatous or leukemic involvement of the testis may result in a diffusely hypoechoic and homogeneous appearance, which may be unilateral (Mazzu et al., 1995). If paratesticular fluid is present, the epididymis and the testicular and epididymal appendages are more easily identified (Fig. 4.36).

Normal testicular blood flow may be demonstrated with color or power Doppler (Barth and Shortliffe, 1997) (Fig. 4.37). Intratesticular blood flow is low velocity with the average peak systolic velocity (PSV) of less than 10 cm/s (Middleton and Thorne, 1989). Intratesticular blood flow is primarily supplied by the testicular artery, which ultimately divides to supply the individual testicular septa. The fibrous septa coalesce to form the mediastinum testis, which is a hyperechoic linear structure seen in the sagittal plane (Fig. 4.38).

FIG. 4.38 The sagittal image of this testis demonstrates a common anatomic finding, the hyperechoic mediastinum testis *(arrows).* The mediastinum testis is a normal structure resulting from the coalescence of the fibrous septa of the testis.

Spectral Doppler can be used to evaluate the intratesticular blood flow: elevated resistive index (RI) greater than 0.6 suggests impaired spermatogenesis (Fig. 4.39) (Biagiotti et al., 2002; Hillelsohn et al., 2013; Pinggera et al., 2008).

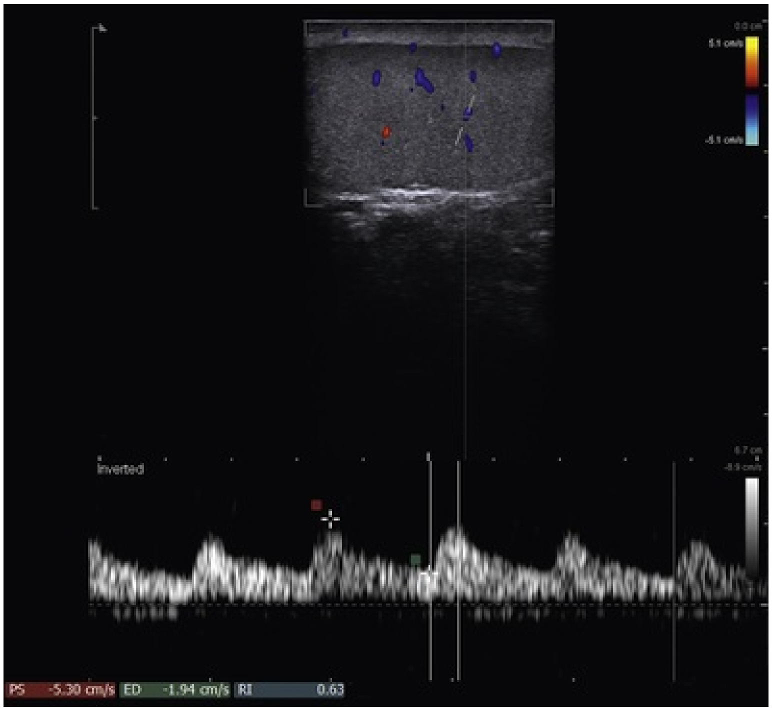

FIG. 4.39 Spectral Doppler analysis of an intratesticular artery demonstrating a peak systolic velocity (PSV) of 5.3 cm/s, an end diastolic velocity of 1.94 cm/s, and a calculated resistive index of 0.63 in a patient with dyspermia.

Procedural Applications

The testis provides easy access for ultrasound localization of internal structures and therefore for percutaneous access. In particular, small nonpalpable lesions can be localized by ultrasound, guiding placement of a needle for percutaneous biopsy or injection of a dye for localization during open biopsy (Buckspan et al., 1989).

Current therapeutic applications using ultrasound guidance include percutaneous testicular sperm aspiration (TESA) (Belker et al., 1998; Friedler et al., 1997; Khadra et al., 2003) or from percutaneous epididymal sperm aspiration (PESA) (Belker et al., 1998; Craft et al., 1995; Lin et al, 2000; Meniru et al., 1998a; 1998b; Pasqualotto et al., 2003; Rosenlund et al., 1998).

Future ultrasound-guided applications may include spermatogonia stem cell transfer to testes devoid of germ cells after gonadotoxic therapies.

Sonoelastography

Two recent studies have used real-time elastography to differentiate benign from malignant testicular lesions because it is postulated that malignant lesions have an increased stiffness resulting from a higher concentration of vessels and cells compared with surrounding tissues. Goddi et al. (2012) assessed 88 testes with 144 lesions and found a 93% positive predictive value, 96% negative predictive value, and 96% accuracy rate (see Fig. 4.19). Aigner et al. (2012) assessed 50 lesions and found a 92% positive predictive value, 100% negative predictive value, and 94% accuracy rate in differentiating malignant from benign lesions. In addition, Li et al. (2012) found that men with nonobstructive azoospermia had a significantly different testicular elasticity compared with patients with obstructive azoospermia and healthy controls with a normal semen analysis. Sonoelastography (see Figs. 4.19 and 4.20) is an exciting innovation in assessing abnormalities on scrotal examination; however, more data are necessary before ruling out surgical intervention based on the findings.

Limitations

Caution should be used when interpreting Doppler flow studies in the evaluation of suspected testicular torsion. The hallmark of testicular torsion is the absence of **intratesticular** blood flow (Fig. 4.40). Paratesticular flow in epididymal collaterals may appear within hours of torsion. Comparison with the contralateral testis should be performed to ensure that the technical attributes of the study are adequate to demonstrate intratesticular blood flow.

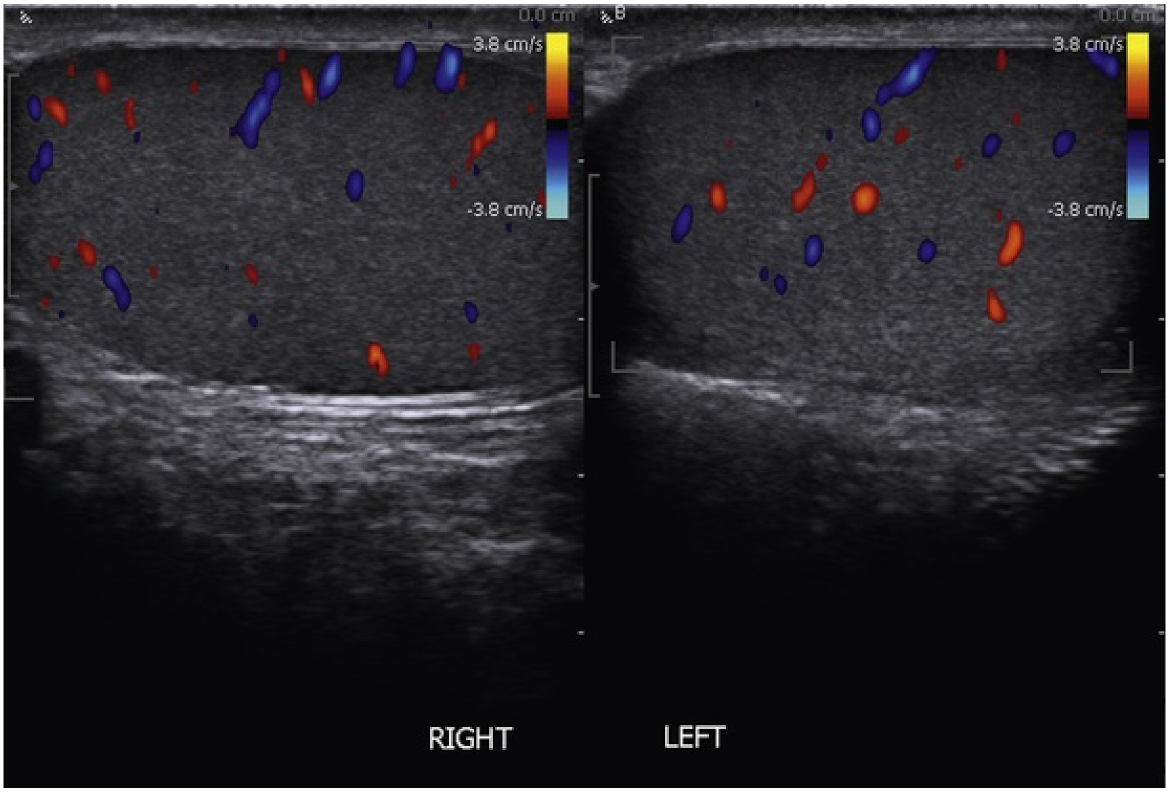

FIG. 4.40 Demonstration of normal bilateral intratesticular blood flow by color Doppler.

Ultrasonography of the Penis and Male Urethra

Ultrasonography of the penis and male urethra provides exquisite anatomic detail and may be used in many cases in lieu of studies requiring ionizing radiation.

Technique

Penile and urethral ultrasonography is best performed with a 12- to 18-MHz linear array transducer for optimum resolution. The technique for penile and urethral ultrasonography includes imaging the phallus in the longitudinal and transverse plane. Ventral and dorsal surfaces of the phallus can be interrogated. As for scrotal ultrasound, the examination is best carried out in a quiet room that is adequately warm for patient comfort. Draping is done to ensure patient privacy. The examination is performed in a systematic fashion beginning at the base of the penis and proceeding distally to the glans. It is possible to get an image of the proximal urethra and corporal bodies by scanning through the scrotum or the perineum.

It may be helpful when evaluating the penile urethra, especially for stricture disease, to inject a sterile gel into the urethra in a retrograde fashion. This distends the urethra and allows better identification of urethral anatomy and the anatomy of the corpus spongiosum.

Indications

1. Evaluation of penile vascular dysfunction
2. Documentation of fibrosis of the corpora cavernosa
3. Localization of foreign body
4. Evaluation of urethral stricture
5. Evaluation of urethral diverticulum
6. Assessment of penile trauma or pain

Normal Findings

Scanning of the external portion of the phallus can be performed either from the dorsal or ventral surface (Fig. 4.41). Transverse scanning of the phallus reveals the two corpora cavernosa dorsally and the urethra ventrally (Fig. 4.42A). The sagittal view of the phallus demonstrates the corpora cavernosa with a hyperechoic, double linear structure representing the cavernosal artery (Fig. 4.42B). The corpus spongiosum is isoechoic to slightly hypoechoic and contains the coapted urethra. The urethra is collapsed except during voiding.

Within the CC the cavernosal artery is shown with a Ca++ in the wall of the artery and posterior shadowing.

Perineal Ultrasound

The more proximal aspects of the urethra and corpora cavernosa are best assessed through a perineal approach by placement of the transducer on the perineum (▶Video 4.2). The bulbar urethra with the bulbar branch of the pudendal artery as well as the proximal cavernosal bodies and the cavernosal branch of the pudendal artery can be visualized (Fig. 4.43A).

(C) Freehand measurement of the area of the bulbocavernosus muscle.

FIG. 4.43

Measurement of the bulbocavernosal (also known as bulbospongiosus) muscle (BCM) through a perineal approach (Fig. 4.43B) is a novel way of assessing androgen receptor sensitivity (Dabaja et al., 2014). The cross-sectional BCM area (Fig. 4.43C) is inversely related to the number of cytosine, adenine, guanine (CAG) repeats. The BCM area has also been shown to be directly related to total testosterone, free testosterone, and bone density as measured by dual-energy x-ray absorptiometry (DEXA) (Gupta et al, 2017).

Transperineal Ultrasound

Transperineal and translabial ultrasound have also been used for evaluation of the pelvic floor for diagnostic and postprocedural follow-up. The anterior, central, and posterior compartments are well visualized. Further, in contrast to a transvaginal approach, they are noninvasive and do not distort the pelvic anatomy (Baxter and Firoozi, 2013).

Excellent visualization of the female bladder, urethra, and pelvic floor can also be obtained via translabial ultrasound. This minimally invasive technique is performed by placing a 5-mHz curved array probe between the labia majora. This allows direct visualization of the urethra, including presence of urethral diverticula, tumors, or foreign bodies. The three compartments of the female pelvis can be examined (Fig. 4.44) with 2D and 3D ultrasound. The relationship between the bladder, urethra, and pelvic musculature can be assessed in real-time in cases of stress urinary incontinence and pelvic organ prolapse.

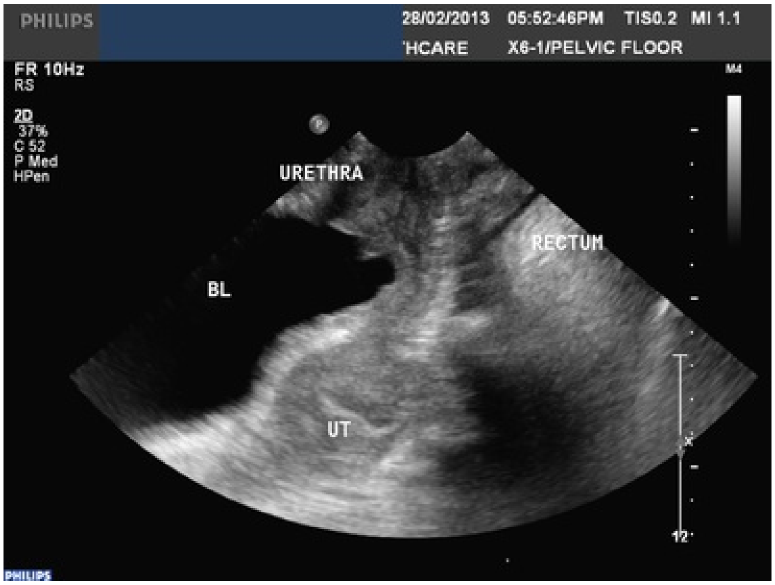

FIG. 4.44 Normal transperineal ultrasound of the female pelvis in the midsagittal plane. The anterior compartment comprises the bladder *(BL)* and urethra, apical compartment comprises the vagina and uterus *(UT),* posterior compartment is the rectum. (Image courtesy Lewis Chan, MD.)

This technique is also useful in assessing complications of urethral slings and pelvic reconstruction. The echogenicity of synthetic sling and meshes makes transperineal ultrasound perfectly well suited to identifying location of a midurethral sling and other meshes in patients with complications such as sling failure, erosion, and de-novo voiding dysfunction (Fig. 4.45).

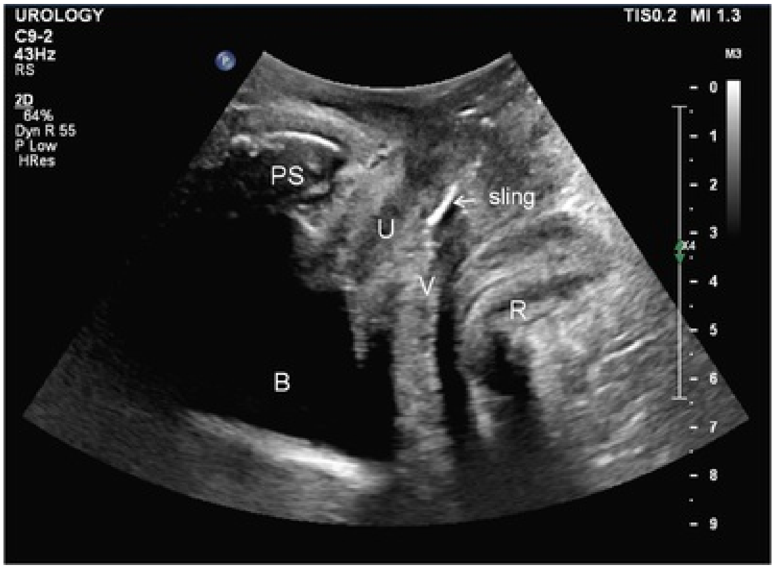

FIG. 4.45 Transperineal ultrasound demonstrating mid-urethral sling *(arrow and label). B,* Bladder; *PS,* pubic symphysis; *R,* rectum; *U,* urethra; *V,* vagina. (Image courtesy Lewis Chan, MD.)

Procedural Applications

The most common application of penile ultrasound is in the evaluation of erectile dysfunction (ED) and penile curvature. Pharmacostimulation provides quantification of cavernosal artery blood flow velocity (Fig. 4.46). Primary criteria for arteriogenic ED include a PSV less than 25 cm/s, cavernosal artery dilation less than 75%, and acceleration time more than 110 msec. Cases of equivocal PSV measurements, particularly when PSV is between 25 and 35 cm/s, included asymmetry of greater than 10 cm/s in PSV between the two cavernosal arteries, focal stenosis of the cavernosal artery, cavernosal artery, and cavernosal-spongiosal flow reversal (Benson et al., 1993).

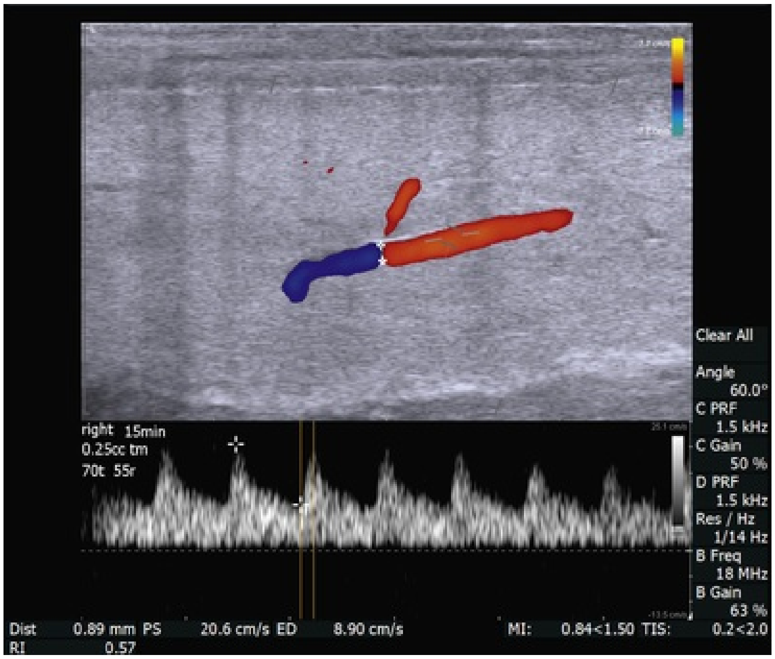

FIG. 4.46 Longitudinal view of the right corpora cavernosa demonstrating peak systolic (PS) and end diastolic (ED) flow velocity in the right cavernosal artery, which measures 0.89 mm in diameter.

In addition, arteriogenic ED has been found to correlate directly with other systemic cardiovascular diseases, coronary artery disease (CAD), and peripheral vascular disease (PVD) in a number of population studies. PSV is the most accurate measure of arterial disease as the cause of ED. The average PSV after intracavernosal injection of vasoactive agents in healthy volunteers without ED ranges from 35 to 47 cm/s, with a PSV of 35 cm/s or greater signifying arterial sufficiency after pharmacostimulation (Broderick and Lue, 1991; Lue et al., 1985; Mueller and Lue, 1988; Pescatori et al., 1994; Schaeffer et al., 2006; "Sexual impotence caused by vascular disease," 1990; Shabsigh et al., 1990). Penile cavernosal artery internal diameter less than 1 mm can often be the first indication of vascular disease. The finding of arteriogenic dysfunction can often provide a window of opportunity (Miner, 2011) to identify and potentially alter the progressive nature of systemic vascular disease (Gazzaruso et al., 2008; Montorsi et al., 2006; Seftel, 2011).

Assessment of penile curvature most often involves palpation and ultrasound interrogation of the pharmacostimulated phallus. However, a palpable plaque is not easily identified (Kalokairinou et al., 2012; Prando, 2009). Often, in many cases, standard B-mode and color Doppler ultrasound does not localize pathology. Sonoelastography (tissue elasticity imaging) is an emerging ultrasound modality that evaluates the stiffness of biologic tissues and localizes these nonpalpable, nonultrasound visualized lesions for potential treatment (Fig. 4.47) (Richards et al., 2013).

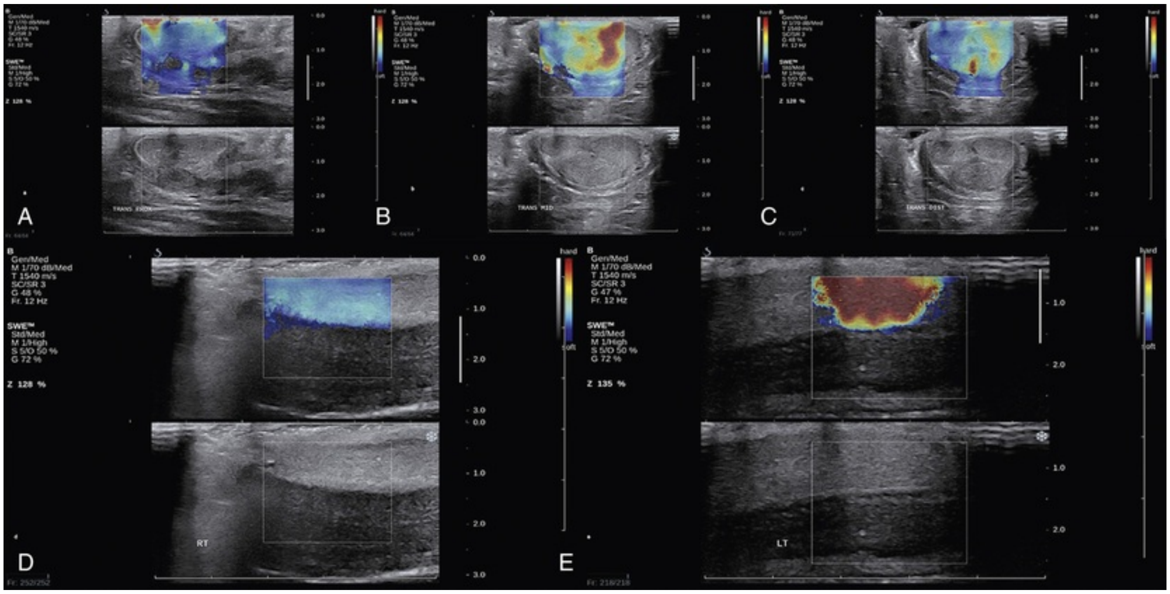

FIG. 4.47 Sonoelastograms (scaled with red more firm and blue less firm) superimposed over transverse B-mode ultrasound images of the (A) proximal, (B) mid, and (C) distal phallus. Sonoelastograms superimposed over parasagittal views of the (D) right and (E) left cavernosal bodies. (From Richards G, Goldenberg E, Pek H, Gilbert BR: Penile sonoelastography for the localization of a non-palpable, non-sonographically visualized lesion in a patient with penile curvature from Peyronie's disease. *J Sex Med* 11:516–520, 2014.)

Limitations

The complete evaluation of the penile urethra, corpora cavernosa, and corpora spongiosum requires a dorsal or ventral interrogation of the exposed phallus as well as a perineal approach to the nonexposed portions of the phallus. This is particularly important in evaluation of the bulbourethra and proximal corpora. In addition, the evaluation of ED requires qualitative and quantitative measurements of blood flow in the penile arteries. Such evaluation requires blood flow measurements before and after the intracavernosal injection of vasoactive substances.

Transrectal Ultrasonography of the Prostate

Transrectal ultrasonography of the prostate (TRUS) is the sonographic imaging procedure most commonly performed by urologists (Trabulsi et al., 2013). It is minimally invasive and provides exquisite anatomic detail of the prostate and periprostatic tissues. Presented here is an overview of transrectal prostate imaging. A comprehensive discussion can be found in Chapter 109. TRUS performed by the urologist enhances patient care by providing a minimally invasive procedure that gives real-time information for a rapid and accurate diagnosis.

Technique

A systematic scan will ensure that a comprehensive examination is performed and appropriately documented. A high-frequency 7.5- to 10-MHz transducer is usually used. This can be a biplane or single-plane transducer (i.e., “end fire” or “side fire”).

It is essential to perform a digital rectal exam **before** inserting the ultrasound probe. Pain or tenderness, rectal stricture, mass, lesion, and/or bleeding that is encountered when performing the rectal exam or when inserting the probe may preclude the TRUS.

After probe insertion, perform a “survey” scan of the prostate from base to apex, including the seminal vesicles and rectal wall. The seminal vesicles are then examined in the transverse plane for comparative evaluation of echogenicity and measurements of seminal vesicle height and ampulla (vas deferens) diameter. Next the midsagittal transverse and longitudinal image of the prostate is examined and the AP, height, and length measurements are taken. Prostate volume, predicted prostate-specific antigen (PPSA) and PSA density (PSAD) can then be calculated usually by formulas already programmed in the ultrasound machine. As in many urologic applications of sonography, color Doppler can add valuable information.

The rectal wall thickness must be evaluated and documented as well as any other notable findings (Trabulsi et al., 2017). Rectal cancer, polyps, and inflammatory processes require further evaluation. The appearance of rectal abnormalities should be documented and possibly a referral made.

Indications

1. Measurement of prostate volume for determination of PSAD
2. Abnormal digital rectal exam

3. Prostatic assessment with sonographic-controlled biopsy
4. Cysts
5. Evaluation for and aspiration of prostate abscess
6. Assessment for suspected congenital abnormality
7. Lower urinary tract symptoms
8. Pelvic pain
9. Prostatitis/prostadynia
10. Hematospermia
11. Infertility (e.g., azoospermia)
    a. Low volume or poorly motile specimen
    b. Cysts
    c. Hypoplastic or dilated seminal vesicle
    d. Impaired motility
    e. Antisperm antibodies

Normal Findings

Echogenicity is best evaluated by comparing the left and right side of the prostate (Fig. 4.48). In the young male, TRUS is often indicated in the evaluation of the subfertile male. The young male prostate is homogenous with zones often difficult to visualize. The “sonographic capsule” can be identified because of the impedance difference between the prostate and surrounding fat. The prominence of the urethra (u) is related to the surrounding low reflectivity of urethral muscles.

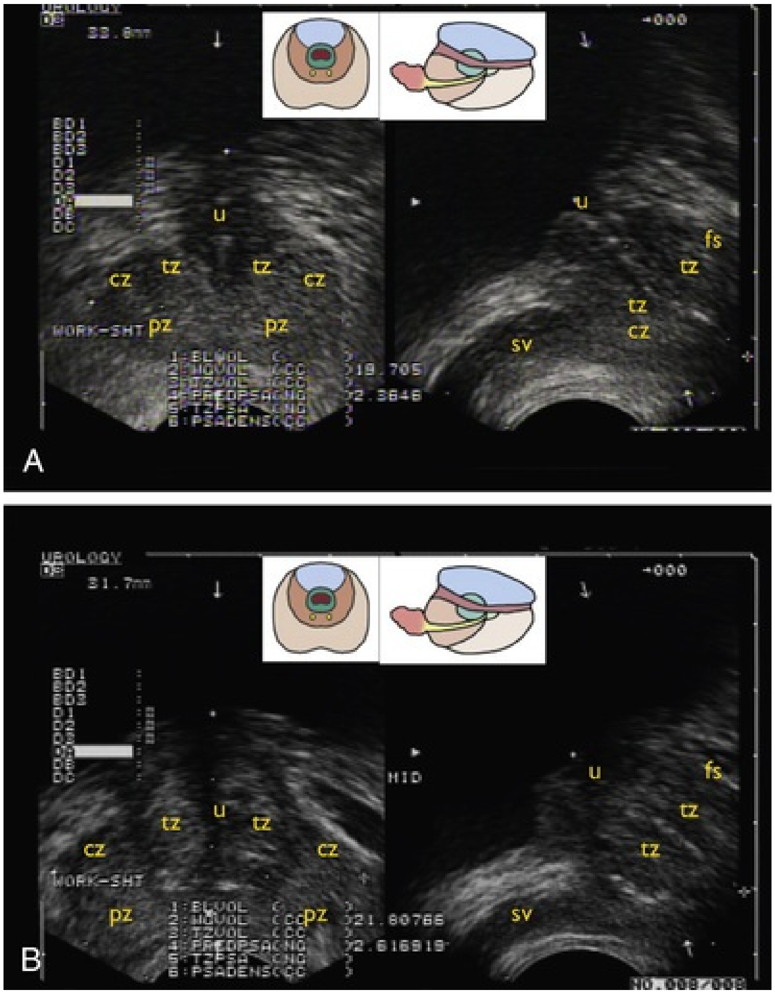

FIG. 4.48 (A) Young male prostate. The peripheral zone *(pz)* is often hyperreflective to the central *(cz)* and transition *(tz)* zones. The cz and tz are difficult to differentiate from each other, and the fibromuscular stroma *(fs)* is positioned anterior to the urethra. (B) Older male prostate. The glandular and stromal elements enlarge, increasing the size of the tz and occasionally the pz. The tz is seen independent of other zones, and the cz is difficult to visualize.

In the young male the peripheral zone (pz) is often hyperreflective to the central zone (cz) and transition zone (tz), although the cz and tz are difficult to differentiate from each other and the fibromuscular stroma (fs) is positioned anterior to the urethra.

In the older male the glandular and stromal elements enlarge, increasing the size of the tz and occasionally the pz. The tz is seen independent of other zones and the cz is difficult to visualize.

The base of the prostate is located at the superior aspect of the prostate contiguous with the base of the bladder. The apex of the prostate is located at the inferior aspect of the prostate continuous with the striated muscles of the urethral sphincter.

Procedural Applications

Transrectal ultrasound-guided biopsy (TRUS/BX) of the prostate is most often initially performed for a specific clinical indication, such as an elevation or change in the PSA or in an abnormal digital rectal examination (Porter, 2013). High-grade prostatic intraepithelial neoplasia (HGPIN) and atypical small acinar proliferation (ASAP) on initial biopsy are considered by some to be indications for immediate or planned repeat biopsy. TRUS/BX may be performed for a rising PSA after initial therapy. In the case of a patient with a rising PSA after radical retropubic prostatectomy, ultrasound and biopsy of the prostatic fossa and vesicourethral anastomosis may be used to diagnose local recurrence. After radiation therapy or cryotherapy, TRUS/BX is employed to diagnose local treatment failure.

Prostatic cyst aspiration is a therapeutic procedure easily performed in the office with minimal patient discomfort. It is often indicated when a large midline cyst obstructs the ejaculatory duct, resulting in dilation of the ejaculatory ducts and/or seminal vesicles. However, refilling of the cyst is common.

Limitations

Bowel preparation is sometimes necessary for imaging. In addition, the patient's body habitus may make it difficult to adequately image the base of the prostate, seminal vesicles, and bladder. Also, current technology limits the diagnostic capabilities of TRUS to anatomic anomalies.

Practice Accreditation

In performing office ultrasound, urologists are committed to ensure that the equipment, sonographers, and protocols provide high-quality diagnostic information. Likewise, patients rightfully expect that the ultrasound exam performed uses equipment that is safe and can effectively image the organ of interest. In addition, third-party payers have, for a multitude of reasons, instituted requirements for practices, including urology practices, to follow to be compensated for their work in providing ultrasound imaging services. How does the urologist sonographer then ensure that the ultrasound exam is compliant with current standards and protocols? One way is through practice accreditation. There are presently two acknowledged accrediting agencies: the American College of Radiology (ACR) and the American Institute for Ultrasound in Medicine (AIUM). The American Urological Association (AUA) and the AIUM have partnered to develop a pathway whereby urology practices can obtain accreditation that is recognized by regulatory authorities and third-party payers.

There are few laws regulating the performance and interpretation of ultrasound examinations. Any licensed physician may purchase an ultrasound machine and begin performing and interpreting sonograms. When an ultrasound exam is indicated, how can patients and their referring physicians be assured of quality?

In 1995 the American College of Radiology (ACR) and the American Institute for Ultrasound in Medicine began to develop programs to accredit ultrasound practices, and the two organizations accredited their first ultrasound practices in 1996. The ACR and AIUM both have pathways to accredit urology practices. The AIUM has worked together with the AUA to develop training guidelines for Urologists and practice parameters for urology practices.

The ACR offers ultrasound practice accreditation in breast, general, gynecologic, obstetric, and vascular ultrasound. The AIUM offers ultrasound practice accreditation in abdominal/general, breast, dedicated musculoskeletal, dedicated thyroid/parathyroid, gynecologic, fetal echocardiography, obstetric, and recently urologic ultrasound.

How does ultrasound practice accreditation differ from AUA board certification? Certification is granted to an individual who has demonstrated a level of knowledge and who continues to meet the requirements necessary to maintain the certification. The individual remains certified regardless of where he or she works. Accreditation is granted to a practice (which may be the practice of a solo practitioner) that demonstrates that all of the individuals in the practice, all the relevant policies and procedures, and equipment and maintenance meet certain requirements. Practices must continue to demonstrate compliance at regular intervals, regardless of whether there are changes in personnel, policies, or equipment. An individual who works in an accredited practice cannot go to another practice and claim that the services provided at the second facility are accredited.

The process of practice accreditation is not without challenges to the urologists and the urology practice. Urologists have traditionally viewed imaging as a tool, very much like a stethoscope, that assists them in providing care for their patients. The process of accreditation changes this by requiring the urologist and the urology practice to expend resources to meet the requirements of accreditation.

However, the accreditation process helps organize the approach to the ultrasound examination and markedly improves quality. This translates into improved diagnostic ultrasound examinations and, in turn, patient satisfaction (Abuhamad and Benacerraf, 2004).

Key Points: Ultrasonography

- An ultrasound wave is a mechanical wave creating alternating areas of compression and rarefaction in tissue.
- Axial resolution improves with increasing frequency of the ultrasound wave.
- Depth of ultrasound penetration decreases with increasing frequency.
- Optimal ultrasound imaging requires trade-offs between resolution and depth of penetration.
- Artifacts may be helpful in the diagnosis of certain conditions.
- The appropriate number of images to be captured for documentation is the number necessary to document a systematic and complete examination and to document relevant pathology.
- The mechanical index and the thermal index are not safety limits.
- The ALARA principle is intended to limit the total energy imparted to the patient during an examination.

- The most important factor in ultrasound safety is the informed operator.
- Angiomyolipoma has a characteristic hyperechoic appearance, but some renal cell carcinomas are also hyperechoic.
- Automated measurement of bladder volume or residual urine, although using ultrasonography, is not an imaging study.
- Sonoelastography extends the ability of ultrasound to detect “hardness” of a lesion.
- The hallmark of testicular torsion is the absence of intratesticular blood flow. However, ultrasound cannot diagnose torsion, only the surgeon (or the pathologist) can.

Urinary Tract Imaging

Basic Principles of Nuclear Medicine

Michael A. Gorin MD, Steven P. Rowe MD

Nuclear medicine is a branch of radiology that utilizes pharmaceutical agents labeled with radionuclides to visualize organ function, treat disease, and characterize molecular processes within cells (Society of Nuclear Medicine and Molecular Imaging, 2018). The last of these applications is commonly referred to as *molecular imaging*. Imaging agents used in nuclear medicine, known as *radiotracers,* are generally administered in subpharmacologic quantities such that they do not perturb the processes that they are being used to measure. Radiotracers emit radioactivity that can be detected by an external sensor unit. Data received by the sensor can then be formatted as an image for interpretation by a nuclear medicine specialist. In contrast, anatomic imaging techniques, such as plain film radiography, computed tomography (CT), magnetic resonance imaging (MRI), and ultrasonography all require an external energy source to generate structural images of the body.

In the field of urology, there are many applications of nuclear imaging. In this chapter, we review the basic principles of nuclear medicine and explore ways in which this specialized form of diagnostic imaging can be used to evaluate the genitourinary tract.

Principles of Single Photon and PET Imaging

Radionuclides that emit low energy gamma photons in the range of 100 to 300 keV can be detected with a gamma camera operating in either planar or tomographic mode (Zanzonico, 2012). The gamma camera itself is composed of several key components: a scintillation crystal (usually made of NaI) that absorbs gamma photons and emits light, photomultiplier tubes that collect and amplify the light emitted by the scintillation crystal, and circuitry that integrates the output from the photomultiplier tubes into information that can be reconstructed as an image. To encode spatial information, a device called a *collimator* is generally placed between the patient and the scintillation crystal. The collimator has a specific geometry that allows gamma photons traveling only in a certain direction to reach the scintillation crystal. When operated in planar mode, photons are detected by the gamma camera at a single angle to the patient. The resulting image from a planar acquisition is a two-dimensional representation of the detected radioactivity.

Three-dimensional images can also be acquired with single-photon imaging. This requires the gamma camera to be slowly rotated around the patient so that photons can be detected at multiple angles of incidence. This is often referred to as *single-photon emission computed tomography (SPECT).* A noncontrast CT scan is typically acquired at the time of SPECT imaging and is used for anatomic localization of the detected radioactivity and for signal attenuation correction (i.e., correction for the fact that signal generated more deeply within the patient is attenuated as photons travel through the body). SPECT may be included as a standard part of an imaging protocol or can be used for problem solving when two-dimensional planar images are inadequate to completely understand a pathologic process. Commonly used radionuclides for single-photon imaging include technetium-99m (^{99m}Tc) and indium-111 (^{111}In) (Table 5.1).

TABLE 5.1

Physical Characteristics of Single-Photon Emitting Radionuclides Mentioned in the Chapter

RADIONUCLIDE	HALF-LIFE (hours)	POSITRON ENERGY IN keV (%)

^{67}Ga	78.3	93 (37), 185 (20), 300 (17), 395 (5)
^{111}In	67.3	171 (90), 245 (94)
^{99m}Tc	6.0	140 (89)

Data from Ziessman HA, O'Malley JP, Thrall JH. *Nuclear medicine: the requisites.* 4th ed; 2013.

Radionuclides that emit positrons can be detected with positron emission tomography (PET) (Basu et al. 2011; Zanzonico, 2012). Emitted positrons travel a short distance before colliding with a nearby electron, causing an annihilation event that leads to the release of two 511 keV photons traveling 180 degrees apart. Images are constructed after the coincident detection of these two high-energy photons. Like SPECT imaging, PET is acquired tomographically and is typically performed in combination with a noncontrast CT, allowing anatomic localization and attenuation correction. Alternatively, an MRI can be acquired at the time of PET imaging in specially designed PET/MRI scanners, which are becoming more common in many large specialty centers (Mannheim et al., 2018). Radionuclides used for PET imaging include carbon-11 (^{11}C), iodine-124 (^{124}I), fluorine-18 (^{18}F), and gallium-68 (^{68}Ga) (Table 5.2).

TABLE 5.2

Physical Characteristics of Positron-Emitting Radionuclides Mentioned in the Chapter

RADIONUCLIDE	HALF-LIFE	POSITRON ENERGY (keV)	RANGE IN SOFT TISSUE (mm)	PRODUCTION SOURCE
^{11}C	20.3 minutes	960	3.9	Cyclotron
^{18}F	109.8 minutes	634	2.3	Cyclotron
^{68}Ga	68.0 minutes	1899	8.9	Generator
^{124}I	4.17 days	1525 (50%) and 2138 (50%)	6.9 and 10.2	Cyclotron
^{89}Zr	78.4 hours	896	3.6	Cyclotron

Data from Serdons K, Verbruggen A, Bormans GM. Developing new molecular imaging probes for PET. *Methods* 2009;48(2):104-111.

Among the described nuclear imaging techniques, PET offers the highest level of spatial resolution (~5 mm vs. ~10 mm for SPECT and ~20 mm for scintigraphy). Additionally, depending on the radiotracer administered, PET typically offers the highest degree of visual conspicuity. This is because the PET detector can filter out photons that lack a coincidentally detected partner, thus minimizing noise. In contrast, any photon passing through the collimator of a gamma camera is assumed to be a true signal. Another relative strength of PET imaging is the ability to quantify the degree of radiotracer uptake within areas of interest through the measurement of standardized uptake values (SUVs) which take into account the total dose of injected radiotracer and patient body mass (Boellaard, 2009). In contrast, single-photon imaging, as currently used clinically, only allows for semiquantitation. A notable limitation of PET is the relatively high cost of this technology, limiting access in many parts of the world. At the present time, the majority of functional imaging tests in urology are performed with scintigraphy, and cancer imaging is most often performed with PET in combination with CT or MRI.

Functional Imaging of the Kidneys

Over the past half century, a number of radiopharmaceutical agents have been developed to allow for the functional assessment of the kidneys (Taylor 2014a, 2014b). Common applications for these agents include measurement of renal blood flow, determination of differential renal function, evaluation for the presence and degree of renal obstruction, and assessment of renal scarring. Accurate interpretation of imaging results relies on a firm understanding of renal physiology and the properties of the available imaging agents.

Relevant Renal Physiology

On average, the kidneys receive 20% of cardiac output. For a healthy individual weighing approximately 70 kg, cardiac output averages 5 L/min, making the total blood volume received by the kidneys equal to approximately 1 L/min. With 60% of blood volume composed of plasma (the liquid component of blood that contains water, glucose, proteins, and electrolytes), renal plasma blood flow (RPF) to the kidneys occurs at a rate of approximately 600 mL/min. It is the job of the kidneys to clear plasma of waste products and to maintain electrolyte balance. Approximately 20% of plasma clearance occurs by passive glomerular filtration, and the remaining 80% occurs by active tubular secretion. The kidneys have the ability to reclaim free water and various electrolytes from fluid in the renal tubules depending on the physiologic needs of the body. The mechanism of clearance from the blood and the timing of excretion from the kidney determines the clinical information that each radiotracer can provide. Although a number of agents have been investigated for functional renal imaging, the radiotracers most commonly used in current clinical practice are technetium-99m diethylenetriaminepentaacetic acid (^{99m}Tc-DTPA), technetium-99m mercaptoacetyltriglycine (^{99m}Tc-MAG3), and technetium-99m dimercaptosuccinic acid (^{99m}Tc-DMSA).

Technetium-99m Diethylenetriaminepentaacetic Acid (^{99m}Tc-DTPA)

DTPA, also known as pentetic acid, is a heavy metal chelator with multiple industrial and medical applications. When radiolabeled with ^{99m}Tc, the resulting compound can be used to evaluate relative RPF to the kidneys and to assess for functional renal obstruction. Upon injection into the bloodstream, ^{99m}Tc-DTPA is extracted by the kidneys entirely through glomerular filtration (Reba et al., 1968). The drug then quickly moves through the renal tubules and is excreted in the urine without being reabsorbed. Because of this agent's mechanism of renal clearance, ^{99m}Tc-DTPA can be used to calculate glomerular filtration rate. This same property, however, leads to high background activity and poor image quality in patients with impaired renal function.

Technetium-99m Mercaptoacetyltriglycine (^{99m}Tc-MAG3)

Similar to ^{99m}Tc-DTPA, ^{99m}Tc-MAG3 is a radiotracer that is excreted in the urine and can be used to determine renal split function and to assess for functional obstruction. However, unlike ^{99m}Tc-DTPA, which is cleared from the plasma via glomerular filtration, ^{99m}Tc-MAG3 is protein bound in circulation and undergoes clearance nearly entirely through tubular secretion (Fritzberg et al., 1986). ^{99m}Tc-MAG3 is therefore not impacted by impaired glomerular filtration and has a higher extraction efficiency than ^{99m}Tc-DTPA. This property results in improved image quality and lower radiation doses to nontarget organs. Additionally, the cost of ^{99m}Tc-MAG3 is considerably less than that of ^{99m}Tc-DTPA. In light of these advantages, ^{99m}Tc-MAG3 has largely become the agent of choice for measuring differences in RPF and to asses for functional obstruction.

Technetium-99m Dimercaptosuccinic Acid (^{99m}Tc-DMSA)

A third commonly used radiotracer for assessment of renal function is ^{99m}Tc-DMSA. After intravenous injection, ^{99m}Tc-DMSA is cleared from the plasma primarily by glomerular filtration (Peters et al., 1988). Once within the lumina of the renal tubules, ^{99m}Tc-DMSA undergoes receptor-mediated endocytosis by the proximal tubular cells. The receptors responsible for the endocytosis of ^{99m}Tc-DMSA are megalin and cubilin (Weyer et al., 2013). Because ^{99m}Tc-DMSA is retained by the proximal tubular cells, this imaging agent is ideally suited for imaging cortical processes such as acute pyelonephritis and renal scarring.

Dynamic Renal Imaging With ^{99m}Tc-MAG3 and ^{99m}Tc-DTPA

As mentioned earlier, both ^{99m}Tc-MAG3 and ^{99m}Tc-DTPA can be used to assess differential renal function and to evaluate for the presence of renal obstruction. This requires imaging to be performed in a dynamic fashion over a period of time. This is in contrast with most anatomic imaging techniques in which a static image is commonly acquired at a single time point. Although the details of a given dynamic imaging protocol may vary by clinical indication, the radiotracer administered, or even institutional practices, a number of common principles apply. Using ^{99m}Tc-MAG3 renal scintigraphy as an example, the basics for acquiring and interpreting dynamic imaging data are reviewed.

Patient Preparation

It is important for patients to be well hydrated on the day of the examination. This will ensure the optimal delivery of radiotracer to the kidneys. Before the examination, one should take note of any medications that the patient may be taking that can impact performance and interpretation of the examination. For example, it is important to note if the patient is taking any blood pressure medications such as diuretics. It is also important to note any known or suspected anatomic abnormalities that may impact patient positioning, setup of the gamma camera, or interpretation of the study. For example, it should be noted if the patient has a horseshoe kidney, renal transplant, or duplication of the urinary tract. Finally, it is important to note whether the patient has a history of neurogenic bladder or bladder outlet obstruction, as this may necessitate the placement of a Foley catheter to decrease retrograde pressure to the kidneys. Similarly, for patients with percutaneous nephrostomy tubes, the tubes are often capped so that the patency of the native ureters can be evaluated.

Dosing and Pharmacokinetics

A dose of 2 to 5 mCi (74 to 185 MBq) of ^{99m}Tc-MAG3 is administered by intravenous push (5 to 10 mCi for ^{99m}Tc-DTPA). With an extraction efficiency of nearly 60%, the peak cortical uptake of the ^{99m}Tc-MAG3 radiotracer is typically observed 3 to 5 minutes after intravenous injection (Eshima and Taylor, 1992). Shortly thereafter, the radiotracer is seen within the renal collecting system. By 10 to 15 minutes, the bladder can be visualized as the radiotracer is excreted in the urine. The typical time from the peak activity to half of the radiotracer being cleared from the collecting system (also known as the *half-clearance time*) is 15 to 20 minutes for a nonobstructed renal unit.

Image Acquisition and Interpretation

Dynamic renal imaging is performed in two phases. In the first phase, known as the *perfusion phase*, RPF to each individual renal unit is measured and compared with flow within the aorta. During this phase, images are acquired every 1 to 2 seconds starting immediately after radiotracer administration. Images are generally collected over a 1-minute period. Regions of interest are drawn over the aorta and each renal unit. Additional regions of interest are drawn just outside of each kidney allowing for background subtraction. Data are recorded as the number of total photon counts, also known as activity, per unit time. These data are plotted on a time activity curve (TAC), with time on the *x*-axis and total activity on the *y*-axis. Activity should be detected in the regions of interest overlying the kidneys within several seconds of detection in the aorta. The shape of the curve for each kidney should roughly match that of the aorta (i.e., brisk upstrokes). A curve with a slow rise to peak suggests poor flow to the kidney and likely underlying poor renal function.

The second phase of dynamic renal imaging is known as the functional phase. During this phase, images are acquired at a slower rate, commonly 1 frame per minute. A comparison of the individual renal curves allows for the determination of relative RPF or renal function. The relative function of each kidney is determined by measuring the area under the TACs between 1 and 3 minutes postinjection of the radiotracer. Fig. 5.1 includes the TACs of a patient with normal split renal function. The curves for each kidney are roughly parallel in both shape and magnitude between 1 and 3 minutes postinjection. Typically, a split function difference of up to 10% is considered to be within normal limits.

FIG. 5.1 Normal ^{99m}Tc-MAG3 renogram of a patient with history of hydronephrosis being evaluated for obstruction. In the upper portion of the figure, a series of 2-second–per–frame flow images demonstrate the movement of radiotracer from the site of injection, to the heart, aorta/renal arteries, and kidneys. A corresponding time-activity curve is shown. The *white curve* reflects activity in the aorta, and the *purple* and *teal curves* reflect radiotracer activity in the kidneys. Note the sharp upstroke of all three lines and that activity in the aorta precedes activity in the kidneys by several seconds. In the lower half of the figure, a series of 2-minute–per–frame images depicts radiotracer activity within the kidneys as it transitions bilaterally into the collecting systems, and then drains down the ureters. In the corresponding time-activity curve, activity within the kidneys peaks at approximately 3 to 4 minutes and then washes out, reaching half-peak approximately 6 to 9 minutes later. The split function of the kidneys is within normal limits, measuring 46% on the left and 54% on the right *(red rectangle).* No evidence of obstruction was present, and no furosemide was administered.

With good function, a healthy kidney will spontaneously clear the radiotracer within 15 minutes of initial injection. In contrast, an obstructed renal unit will show retention of radiotracer in the collecting system. This retention will lead to a gradually upsloping TAC with no peak during the acquisition. It is important to note that some patients may experience delayed clearance of radiotracer from the renal pelvis although they do not have a truly obstructed system. In many of these patients, the collecting system and ureter are patulous as a result of a previously repaired obstructive process such as a ureteropelvic junction obstruction. To differentiate these patients from those with obstruction, the diuretic furosemide can be administered. The recommended dose of intravenous furosemide in adults is 0.5 mg/kg body weight to a maximum of 40 mg, although higher doses can be used in patients with impaired renal function who may not respond to a 40-mg dose. A post-furosemide half-clearance time of less than 10 minutes is consistent with a patulous nonobstructed system, whereas a half-clearance time of more than 20 minutes is generally consistent with obstruction. A half-clearance time between 10 to 20 minutes is considered indeterminate, and further evaluation is warranted. Although these values are fairly well agreed on, currently there is little consensus as to the most appropriate timing of furosemide administration (O'Reilly, 2003; Durand et al., 2008). At our institution, furosemide is given 15 minutes after radiotracer injection. Others, however, administer the diuretic at the start of, or 15 minutes before, image acquisition. It is critical for the urologist to review the report that accompanies any ^{99m}Tc-MAG3 or ^{99m}Tc-DTPA study to understand if and when a diuretic was administered.

Figs. 5.1, 5.2, and 5.3 include example TACs for patients imaged with ^{99m}Tc-MAG3. The legend for each figure includes a detailed interpretation of the test.

FIG. 5.2 ^{99m}Tc-MAG3 renogram of a patient with a history of bilaterally repaired ureteroceles and persistent hydronephrosis without functional obstruction. (A) In the upper portion of the panel, a series of 2-second–per–frame flow images demonstrate the movement of radiotracer from the site of injection, to the heart, aorta/renal arteries, and kidneys. A corresponding

time-activity curve is shown. Note that the *purple curve,* representing the right kidney, has less brisk upstroke than the *teal curve* of the left kidney, suggesting decreased function on the right. In the lower half of the figure, a series of 2-minute–per–frame images depicts radiotracer activity within the kidneys as it transitions bilaterally into the collecting systems, and then drains down the ureters. In the corresponding time-activity curve, peak radiotracer uptake in the kidneys is shown to be significantly delayed up to approximately 11 to 14 minutes. Washout is also delayed, with curves for both kidneys slowly decreasing over time. Obstructed systems will often show continued increase in uptake throughout the initial 30 minutes of the examination, so this pattern is perhaps more typical of a patulous but nonobstructed system. The split function of the kidneys is also abnormal, measuring 67% on the left and 33% on the right *(red rectangle)*. (B) Given the delayed washout, 40 mg of intravenous furosemide was administered. In the upper portion of the panel, the 1-minute–per–frame images demonstrate significant washout after administration of furosemide. This is confirmed in the time-activity curve, where both collecting systems drain promptly (half-clearance time of 5 minutes on the left and 6.2 minutes on the right). Less than 10 minutes is diagnostic of a nonobstructed system.

FIG. 5.3 ^{99m}Tc-MAG3 renogram of a patient with right-sided renal obstruction. (A) In the 2-second–per–frame flow images at the top of the panel, the left kidney appears much better perfused than the right kidney. This is borne out in the time-activity curve in the upper half of the panel in which the *teal curve* representing the left kidney has a significantly sharper upstroke relative to the *purple curve* of the right kidney. The *white curve* of the aorta is irregular and unreliable because of the abnormal course of the aorta caused by the patient's scoliosis. In the bottom half of the panel, the 2-minute–per–frame images demonstrate normal transit of radiotracer through the left kidney parenchyma and into the collecting system, with drainage to the bladder. This is shown by the *teal curve* of the left kidney on the time-activity curve. The right kidney, which appears smaller and has a central photopenic area corresponding to a dilated renal pelvis, demonstrates increasing uptake throughout the study with very slow transit into the collecting system. This is shown by the *purple curve* of the right kidney in the time-activity curve. A markedly abnormal split function is present, measuring 79% on the left and 21% on the right *(red rectangle).* (B) Given the obstructive pattern of the right kidney, 40 mg of intravenous furosemide was administered. The 1-minute–per–frame images in the upper portion of the panel demonstrate no significant clearing of radiotracer from the left renal collecting system after furosemide administration. This is also seen in the time-activity curve, where the *teal curve* representing the left kidney is nearly horizontal. The lack of response to furosemide is diagnostic of an obstructed collecting system.

Additional Applications of ^{99m}Tc-MAG3 and ^{99m}Tc-DTPA Scintigraphy

Evaluation of Renal Vascular Hypertension

To maintain a near-constant rate of glomerular filtration, the kidneys employ a system of vascular autoregulation that is modulated by release of renin from the juxtaglomerular cells of the nephron (Beevers et al., 2001). In cases in which arteriole blood flow is perceived as low, renin acts to convert the protein angiotensinogen to angiotensin I. This peptide hormone is further converted by angiotensin-converting enzyme in the lung to angiotensin II, which stimulates the release of aldosterone from the adrenal glands and acts on the efferent arterioles of the glomerulus to raise filtration pressure. Additionally, angiotensin II causes peripheral vasoconstriction resulting in increased systemic blood pressure. In individuals with renal artery stenosis, the renin-angiotensin-aldosterone system is in a state of constant activation resulting in hypertension and, with time, glomerular sclerosis (Safian and Textor, 2001; Dworkin and Cooper, 2009). Renal scintigraphy can be used to differentiate between renal vascular hypertension and essential hypertension. Clues to the presence of renal vascular hypertension include early age of onset, hypertension that is resistant to multiple medical therapies, and a bruit on physical examination.

When evaluating for renal vascular hypertension, dynamic imaging with either ^{99m}Tc-MAG3 or ^{99m}Tc-DTPA can be performed. ^{99m}Tc-DTPA, however, is typically used for this application, as it is cleared from the blood exclusively by glomerular filtration. During the course of this evaluation, patients are imaged using a 2-day protocol. On the first day of imaging, patients are administered a dose of oral captopril, an angiotensin-converting enzyme inhibitor, and then undergo standard dynamic renal scintigraphy. In cases of renal artery stenosis, one will observe slow uptake and low peak activity after captopril administration. For those with an abnormal curve, a second study is performed 1 to 2 days later, with the patient holding any angiotensin-converting enzyme inhibitors or calcium channel blockers. An improvement in renal function by 10% is associated with a high probability of renal vascular hypertension, and these patients would likely be best served by angioplasty or other surgical intervention (Mann et al., 1991; Bubeck, 1993). With the widespread availability of cross-sectional imaging, including CT angiography, MR angiography, and ultrasonography with Doppler, the use of captopril scintigraphy has decreased over time.

Renal Transplant Evaluation

Dynamic renal scintigraphy with either ^{99m}Tc-MAG3 or ^{99m}Tc-DTPA can also be used to evaluate renal transplant patients for acute rejection or delayed graft function secondary to prolonged ischemia during organ harvesting (Dubovsky et al., 1999). It is critical to differentiate between these two processes, as their management differs considerably. Although renal biopsy is the best differentiator of the two, dynamic renal imaging can be used to gain clues as to the underlying pathology. More specifically, acute rejection is characterized by decreased renal perfusion, and for delayed graft function normal perfusion is maintained. Additionally, on serial imaging, acute rejection will worsen with time, whereas in delayed graft function longitudinal improvement is typically observed. A challenge of using dynamic renal imaging in this context is the fact that transplant patients often have overlapping causes of renal failure. Furthermore, some patients with renal ischemia will progress to chronic impairment of the kidney, in which case serial imaging can be misleading. Thus, it is important to understand the full clinical context of a patient being imaged for this indication. One additional use of dynamic renal imaging in transplant patients is to evaluate for an anastomotic leak, which on delayed imaging can be seen as a collection of radioactivity outside of the kidney. This is particularly helpful in this patient population who are often unable to receive iodinated contrast.

Assessment of Vesicoureteral Reflux

Vesicoureteral reflux (VUR) is a condition in which urine flows in a retrograde fashion from the bladder to the upper urinary tracts (Peters et al., 2010; Tekgul et al., 2012). This occurs commonly in children and can result in ascending infections of the kidneys and eventual loss of renal function. The presence and degree of reflux can be monitored with renal scintigraphy (Piepsz, 2002). This can be performed by administering ^{99m}Tc-MAG3 or ^{99m}Tc-DTPA and then asking the patient to void once the radiotracer has accumulated in the bladder. Alternatively, and more commonly, a solution of ^{99m}Tc-sulfur colloid can be instilled directly into the bladder. It is important to note that fluoroscopic voiding cystourethrography, and not nuclear scintigraphy, should be used in the initial screening for VUR (Tekgul et al., 2012). The reason for this is that scintigraphy provides little anatomic information, and children with a history of urinary tract infections should also be evaluated for posterior urethral valves (in males) and bladder diverticula, conditions that can only be detected with the combined anatomic and functional information from a fluoroscopic voiding cystourethrogram. Nuclear voiding cystography should be used instead to follow patients with reflux. Indeed, this imaging test is often preferred over contrast cystography because of its higher sensitivity for detecting subtle VUR and its lower associated radiation doses (Lebowitz, 1992).

Renal Cortical Imaging With ^{99m}Tc-DMSA

As noted earlier, ^{99m}Tc-DMSA is retained by proximal tubular cells of the kidney allowing for visualization of the renal cortex. Patients undergoing this examination should be prepared in a manner similar to the earlier description for dynamic renal imaging. A dose of the radiotracer in the amount of 50 μCi/kg for children or 5 mCi for adults is then administered intravenously, and images are acquired 2 hours later with either a pinhole collimator or gamma camera operating in SPECT mode. Because ^{99m}Tc-DMSA clearance is dependent on glomerular filtration, the imaging time may need to be modified in patients with renal failure.

Renal cortical imaging is mainly used to evaluate for suspected pyelonephritis and to detect renal scarring. In a normal ^{99m}Tc-DMSA study, the renal parenchyma should appear homogeneous and smooth. Areas with acute inflammation or infection will appear as defects with low levels of radiotracer uptake. Similarly, renal scarring will also appear as areas without radiotracer uptake. However, areas of scarring will typically have sharper borders and are commonly seen in small atrophic kidneys. Although clinical context is the best way to differentiate between acute inflammation and scarring, serial imaging can be helpful in discerning between these two processes. In cases of pyelonephritis, one can often see resolution of the photopenic area, whereas with scar the area devoid of radiotracer uptake will persist. A period of typically 6 months is recommended between scans.

Key Points

- The most commonly used radiopharmaceutical agents for nuclear imaging of the kidneys are technetium-99m diethylenetriaminepentaacetic acid (^{99m}Tc-DTPA), technetium-99m mercaptoacetyltriglycine (^{99m}Tc-MAG3), and technetium-99m dimercaptosuccinic acid (^{99m}Tc-DMSA).
- ^{99m}Tc-DTPA and ^{99m}Tc-MAG3 are used to measure renal blood flow, determine differential renal function, and evaluate for the presence and degree of renal obstruction.
- ^{99m}Tc-DTPA is cleared by glomerular filtration, whereas ^{99m}Tc-MAG3 is cleared by tubular secretion.
- ^{99m}Tc-MAG3 is preferred at most centers over ^{99m}Tc-DTPA because it has a higher extraction efficiency and is less affected by changes in renal function.
- ^{99m}Tc-DMSA is retained by cells of the proximal renal tubules and is used to evaluate for infection and the presence renal scarring.
- ^{99m}Tc-DTPA and ^{99m}Tc-MAG3 can also be used to evaluate renovascular hypertension, transplant graft function, and vesicoureteral reflux.

Infection Imaging

Although infections of the genitourinary tract can often be readily identified on the basis of clinical signs, symptoms, and localizing culture data, this is not always the case. Pediatric patients and individuals with neurologic disorders or compromised immunity potentially pose a challenge in this regard. Within the field of nuclear medicine, a host of radiopharmaceuticals have been developed to aid with the identification and localization of infectious and inflammatory processes.

^{99m}Tc-DMSA is the most widely used radiopharmaceutical agent for imaging infections of the kidney, although its role has decreased with the widespread availability of CT. As previously noted, this radiotracer will show decreased uptake in areas of active pyelonephritis. On follow-up imaging, these areas will show resolution with homogeneous uptake. In contrast, areas of renal scarring will have continued photopenia that corresponds to alterations in the renal contour compatible with thinned cortex. These foci can also be found in patients with a history of VUR who may have never had a documented bout of pyelonephritis. Identification of cortical scarring is important as it predisposes patients to the development of hypertension and chronic kidney disease (Fillion et al., 2014).

Leukocytes labeled with ^{111}In-oxine can also be used for imaging infections of the kidney. Oxine is a lipid-soluble complex that chelates ^{111}In and passively diffuses into leukocytes. For this test, white blood cells are first collected from the patient by drawing approximately 50 mL of venous whole blood. Erythrocytes are then removed from the collected blood sample, and the remaining white blood cells are labeled with ^{111}In-oxine under a laminar flow hood. After labeling, the cells are injected back into the patient. The labeled white blood cells will normally accumulate in the liver, spleen, and bone marrow, with other sites of uptake generally indicating the presence of active infection. Blood pool activity clears with a half-life of ~7.5 hours, and so it is recommended that whole-body scintigraphy be performed approximately 24 hours after ^{111}In-oxine-tagged white blood cell injection. Given the long decay half-life of ^{111}In (67.3 hours), imaging at 24 hours is very feasible.

Alternatively, leukocytes can be labeled with ^{99m}Tc-hexamethyl-propyleneamine oxime (^{99m}Tc-HMPAO), a lipid-soluble neutral complex that rapidly diffuses into cells. The use of ^{99m}Tc as the radionuclide results in improved image quality over ^{111}In. ^{99m}Tc-HMPAO can be seen, however, being cleared in urine and the hepatobiliary system, and this property makes use of this imaging agent challenging when evaluating for sites of infection in close proximity to the genitourinary tract (versus ^{111}In-oxine-labeled white blood cells, which have no normal uptake anywhere in the lower abdomen) (Brown et al., 1994; Forstrom et al., 1995). Imaging with ^{99m}Tc-HMPAO–tagged white blood cells is typically undertaken at 1 to 2 hours postreinfusion to minimize the amount of interfering radioactivity in the bowel, renal collecting system, ureters, and bladder. Despite the potential disadvantages, ^{99m}Tc-HMPAO–tagged white blood cells are preferred for pediatric patients because of more favorable dosimetry (Brown et al., 1994). It is worth noting that regardless of the radiolabeling method, tagged leukocyte imaging cannot be used when assessing a transplant kidney because a large fraction of the white blood cells will accumulate in the renal graft, which is seen as non-self by the white blood cells.

Another application of infection imaging in the urologic patient is the evaluation of intra-abdominal infections. This is particularly helpful for patients without localizing symptoms or convincing findings of a collection on conventional imaging. In this situation, radiolabeled white blood cells labeled with ^{111}In-oxine are particularly helpful. Intra-abdominal signal with this test has a high specificity for a true infection (Mountford et al., 1990).

One last radiopharmaceutical agent worthy of mention that can be used for the applications mentioned earlier is ^{67}Ga-citrate. This radiotracer binds to transferrin and is transported to areas of inflammation in the body (Ohkubo et al., 1989). Sites of inflammation can then be identified with single-photon imaging. Shortcomings of this radiotracer are its high level of nonspecific accumulation in soft tissues, need for delayed imaging up to 48 to 72 hours, and high cost. Like many radiotracers based on a metabolic process in the body, ^{67}Ga-citrate lacks specificity, and uptake can be seen in many neoplastic processes in addition to infection.

Molecular Imaging of Genitourinary Malignancies

Within the field of oncology, molecular imaging is most commonly performed using the PET radiotracer 2-deoxy-2-[^{18}F]fluoro-D-glucose (^{18}F-FDG) (Farwell et al., 2014). ^{18}F-FDG is a glucose analogue that is taken up by metabolically active cells via GLUT transporters (Brown et al., 1996). Once within the cell, ^{18}F-FDG is phosphorylated by the glycolytic enzyme hexokinase, preventing diffusion back across the cell membrane. The trapped ^{18}F-FDG molecules, which are missing a 2-hydroxyl group, cannot undergo further metabolism and remain intact allowing for their detection with PET imaging.

^{18}F-FDG accumulates in cells of metabolically active organs including the brain and kidneys. Additionally, ^{18}F-FDG is taken up by malignant cells, which commonly shunt energy production from oxidative phosphorylation to lactic acid fermentation, a phenomenon referred to as the *Warburg effect* or *aerobic glycolysis* (Bensinger and Christofk, 2012). A number of genitourinary malignancies can be successfully imaged with ^{18}F-FDG PET including urothelial carcinoma, renal cell carcinoma (RCC), squamous cell carcinoma of the penis, and testicular germ cell tumors. Because the genitourinary tract is partially obscured by urinary excretion of ^{18}F-FDG, imaging with this radiotracer is typically reserved for the detection of distant sites of disease. Of note, prostate cancer, the most common genitourinary malignancy, is unique in that it uncommonly shunts energy production toward aerobic glycolysis and therefore is poorly visualized with ^{18}F-FDG PET (Zadra et al., 2013; Jadvar, 2013).

A multitude of other PET radiotracers have been developed for cancer imaging, including additional agents that accumulate on the basis of increased cellular metabolism and compounds that target specific cancer-associated proteins. The use of ^{18}F-FDG and other PET radiotracers for imaging genitourinary malignancies is reviewed.

Bladder Cancer

^{18}F-FDG is the most widely studied PET radiotracer for imaging urothelial carcinoma of the bladder (Fig. 5.4). In a meta-analysis that included data from

14 studies, the pooled sensitivity of ^{18}F-FDG PET for preoperative lymph node staging was 57% (95% CI, 49% to 64%), with a pooled specificity of 92% (95% CI, 87% to 95%) (Ha et al., 2018). Current guidelines, however, do not support the routine use of ^{18}F-FDG PET in patients with otherwise clinically localized bladder cancer, as it remains unclear if the detection of extravesical disease on molecular imaging alone changes outcomes in these patients (Chang et al., 2017; Alfred Witjes et al., 2017). According to guidelines from the American Urological Association, PET imaging of bladder cancer is only indicated in cases of equivocal conventional imaging or as a confirmatory test when biopsy of a conventional imaging finding is not possible (Chang et al., 2017). Additionally, available data suggest that MRI may provide a higher level of sensitivity for detecting lymph node metastases, while also maintaining the ability to accurately visualize localized disease within the bladder (Crozier et al., 2018). Indeed, multiparametric MRI is increasingly being used to image bladder cancer (Woo et al., 2017; van der Pol et al., 2018; Panebianco et al., 2018).

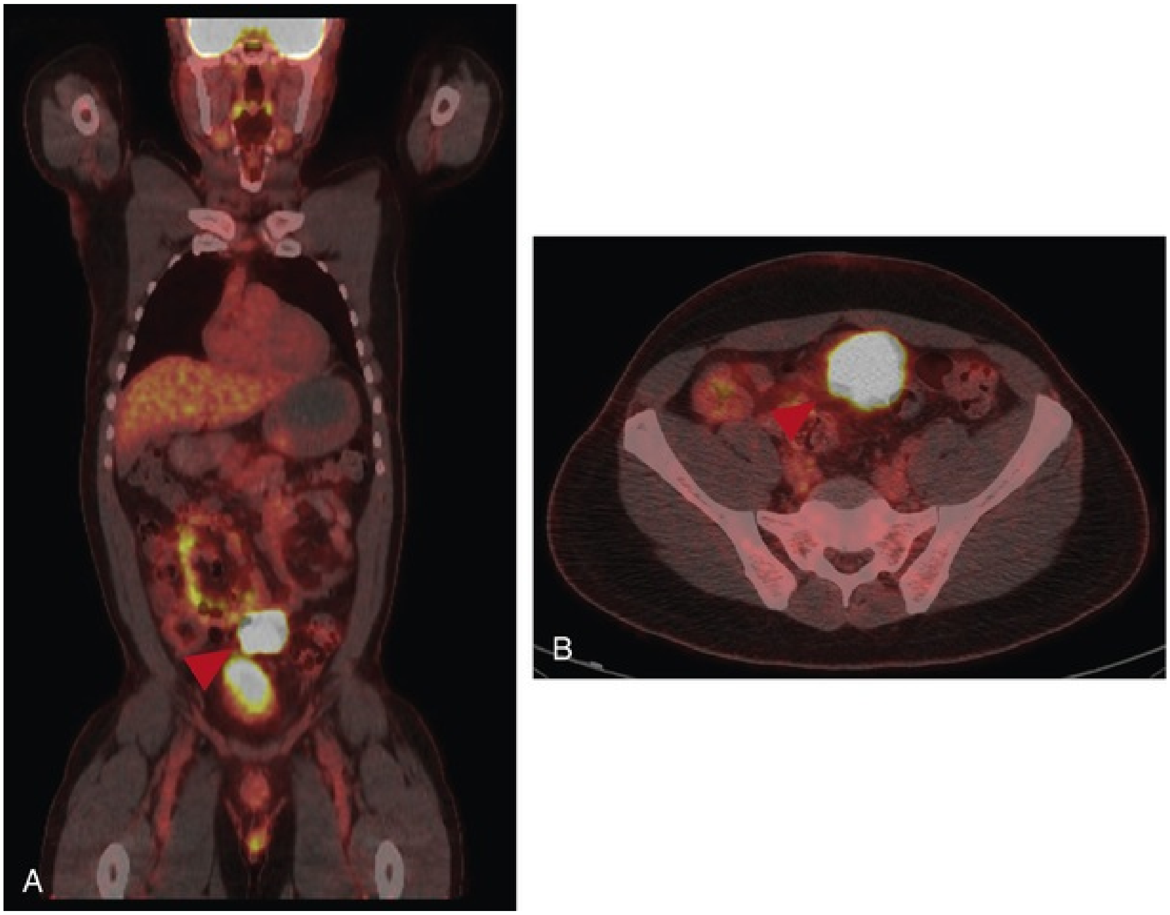

FIG. 5.4 ^{18}F-FDG PET/CT of a patient with metastatic urothelial carcinoma of the bladder. Coronal (A) and axial (B) fused PET/CT images. The *red arrowheads* point to a large FDG-avid soft tissue mass within the anterior pelvis.

^{18}F-FDG PET can also be used to image urothelial carcinoma of the upper urinary tract (Asai et al., 2015; Tanaka et al., 2016). As with bladder cancer, this imaging modality appears to be most useful for detecting distant sites of disease. Current guidelines state that the mainstay of imaging localized upper tract urothelial carcinoma is CT urography; however, little guidance is provided on imaging distant sites of disease (Roupret et al., 2018). Because of the rare nature of upper tract urothelial carcinoma, large studies evaluating the clinical utility of ^{18}F-FDG PET imaging of this malignancy are limited. Thus, ^{18}F-FDG PET should be used sparingly in cases of upper tract urothelial carcinoma, and guidelines for imaging bladder cancer should likely be applied (Chang et al., 2017).

Although the use of ^{18}F-FDG PET for imaging of urothelial carcinoma is limited at the current time, emerging data suggest a potential role for this imaging modality to aid in disease prognostication. For example, Vind-Kezunovic et al. found that SUV_{max} on preoperative ^{18}F-FDG PET/CT was independently associated with the risk for bladder cancer recurrence after radical cystectomy with extended lymph node dissection (Vind-Kezunovic et al., 2017). Additionally, several studies have shown the potential for ^{18}F-FDG PET to predict histologic response to induction or neoadjuvant chemotherapy (Kollberg et al., 2017; Soubra et al., 2018). Additional work, however, is required to more fully understand the clinical benefits of ^{18}F-FDG imaging as a tool for disease prognostication.

Other PET radiotracers have been studied for imaging urothelial carcinoma. Two particularly promising agents are ^{11}C-chole and ^{11}C-acetate, which are positron-emitting radiolabeled cell membrane building blocks that localize to rapidly dividing cells (Kim et al. 2018). Both of these radiotracers have shown potentially higher levels of sensitivity than ^{18}F-FDG; however, neither is currently approved for imaging urothelial carcinoma, and their adoption has been hampered by the short 20.9-minute half-life of ^{11}C.

Kidney Cancer

Like urothelial carcinoma, metastatic RCC can be successfully imaged with ^{18}F-FDG PET, albeit with limited gains beyond anatomic imaging techniques. A meta-analysis of 14 studies reported an overall sensitivity of 86% (95% CI, 88% to 93%) and a specificity of 88% (95% CI, 84% to 91%) for ^{18}F-FDG PET to detect sites of recurrent or metastatic RCC (Ma et al., 2017). This imaging test appears to have the highest level of sensitivity for detecting sites of extrarenal disease in cases of type II papillary RCC (Nakatani et al., 2011; Shuch et al., 2014). Current guidelines, however, recommend against the routine use of ^{18}F-FDG PET for staging or follow-up of RCC, as the clinical benefits remain unclear, and most cases of RCC are the clear cell subtype which shows lower levels of ^{18}F-FDG uptake (Donat et al., 2013; Ljungberg et al., 2015).

Novel radiotracers targeting the cell surface protein carbonic anhydrase IX (CAIX)—a molecule that is near universally expressed by clear cell RCC but not by other renal tumor histologies—are likely in the future to play a large role in molecular imaging of RCC. To date, the most promising agent targeting CAIX is the monoclonal antibody girentuximab, also known as G250. The application of CAIX-based PET imaging that has been most actively pursued is the differentiation of localized clear cell RCC apart from other renal tumor histologies (Divgi et al., 2007, 2013). In a large phase III trial, PET imaging with ^{124}I-girentuximab PET/CT had a sensitivity of 86.2% (95% CI, 75.3% to 97.1%) and a specificity of 85.9% (95% CI, 69.4% to 99.9%) for differentiating localized clear cell RCC from other renal tumor histologies (Divgi et al., 2013). This outperformed contrast-enhanced CT, which had a sensitivity of 75.5% (95% CI, 62.6% to 88.4%) and a specificity of 46.8% (95% CI, 18.8% to 74.7%). Despite these promising results, girentuximab is not yet approved for routine human use, as the results of a confirmatory phase III trial are pending.

While the urologic community awaits the approval of a PET radiotracer to aid in the histologic characterization of localized renal tumors, the SPECT imaging agent ^{99m}Tc-sestamibi is already available off-label for this application. This radiotracer, which is a lipophilic cation that binds to cells with high mitochondrial content, is approved by the United States Food and Drug Administration (FDA) for breast and myocardial imaging (Travin and Bergmann, 2005; Schillaci et al., 2013). Additionally, ^{99m}Tc-sestamibi is widely used for imaging parathyroid adenomas (Judson and Shaha, 2008) and has recently been shown to accumulate in oncocytic renal tumors with high levels of mitochondrial content such as benign oncocytomas (Fig. 5.5) (Gormley et al., 1996; Rowe et al., 2015; Gorin et al., 2016b; Tzortzakakis et al., 2017). In the largest study to date evaluating this imaging modality, Gorin et al. found a sensitivity of 87.5% (95% CI, 47.4% to 99.7%) and a specificity of 95.2% (95% CI, 83.8 to 99.4%) for differentiating benign renal oncocytomas and hybrid oncocytic/chromophobe tumors from other renal tumor histologies (Gorin et al., 2016b). Although these results are promising, the worldwide literature on ^{99m}T-sestamibi SPECT/CT imaging of renal tumors remains small, and the clinical adoption of this test has been rather limited to date.

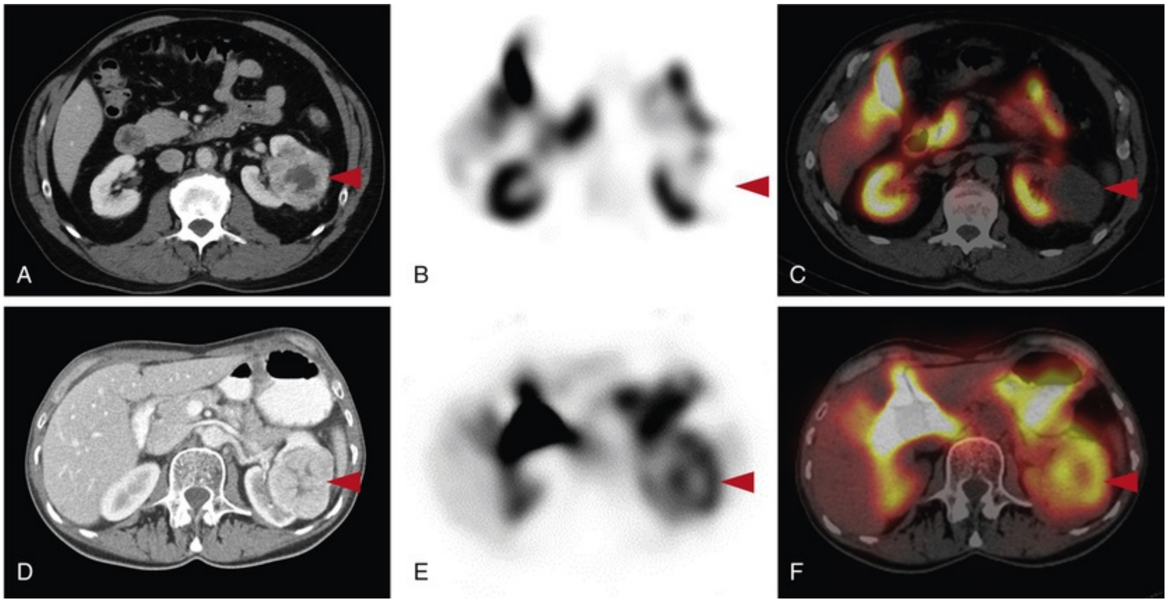

FIG. 5.5 Differentiation of a localized clear cell RCC (A to C) from a benign renal oncocytoma (D to F) using ^{99m}Tc-sestamibi SPECT/CT. (A) Axial, contrast-enhanced CT image demonstrates a heterogeneous mass in the left kidney *(red arrowhead).* Axial ^{99m}Tc-sestamibi SPECT (B) and axial ^{99m}Tc-sestamibi SPECT/CT (C) images show no evidence of radiotracer uptake in the tumor *(red arrowheads).* The mass was resected and was found to be a clear cell RCC. (D) Axial, contrast-enhanced CT image showing another left-sided heterogeneous renal mass *(red arrowhead).* Axial ^{99m}Tc-sestamibi SPECT (E) and axial ^{99m}Tc-sestamibi SPECT/CT (F) images show that the mass has intrinsic radiotracer uptake, with the highest uptake in those parts of the mass with the most avid enhancement *(red arrowheads).* A subsequent renal mass biopsy confirmed the mass to be most consistent with a renal oncocytoma.

Prostate Cancer

As noted earlier, ^{18}F-FDG has little role in imaging prostate cancer. Instead imaging is most commonly performed with a combination of contrast-enhanced CT, MRI, and bone scintigraphy with ^{99m}Tc-methylene diphosphonate, a compound that has affinity for hydroxyapatite crystals in areas of increased osteoid formation. PET imaging with Na^{18}F does offer a more sensitive alternative to bone scan; however, this radiotracer suffers in terms of specificity because of its similar mechanism of uptake to ^{99m}Tc-methylene diphosphonate (Langsteger et al., 2016). Overall, the available combination of traditional modalities for prostate cancer imaging lacks the required sensitivity and specificity for detecting small volume sites of disease. As a result, a number of targeted radiotracers have been developed for PET imaging of prostate cancer (Table 5.3).

TABLE 5.3

PET Radiotracers Used for Prostate Cancer Imaging

NAME OF AGENT	MECHANISM OF UPTAKE	FDA APPROVED?	APPROVED INDICATION
Na^{18}F	Exchanges with hydroxyl groups on hydroxyapatite at areas of bone turnover	Yes	Imaging of bone to define areas of altered osteogenic activity
^{18}F-FDG	Glucose analogue that is taken up by glycolytically active cells	Yes	Assessment of abnormal glucose metabolism to assist in the evaluation of malignancy in patients with known or suspected abnormalities found by other testing modalities, or in patients with an existing diagnosis of cancer
^{11}C-choline	Choline analogue that is taken up by metabolically active cells undergoing phospholipid synthesis	Yes	Imaging of men with suspected prostate cancer recurrence and noninformative bone scintigraphy, CT, or MRI
^{18}F-FACBC	Amino acid analogue that is taken up by metabolically active	Yes	Imaging of men with suspected prostate cancer recurrence based on an elevated PSA level after prior

	cells undergoing protein synthesis		treatment
^{68}Ga-PSMA-11	Small molecule inhibitor of PSMA	No	N/A
^{18}F-DCFPyL	Small molecule inhibitor of PSMA	No	N/A
^{68}Ga-RM2	Synthetic gastrin-releasing peptide receptor antagonist	No	N/A

Data from Joice GA, Rowe SP, Pienta KJ, Gorin MA. Oligometastatic prostate cancer: shaping the definition with molecular imaging and an improved understanding of tumor biology. *Curr Opin Urol* 2017;27(6):533–541.

The first radiotracer to be approved by the FDA specifically for prostate cancer imaging was ^{11}C-choline. This agent has been shown to provide added value over conventional imaging in the detection of otherwise-occult pelvic lymph nodes in patients undergoing radical prostatectomy (Mapelli and Picchio, 2015; Castellucci et al., 2017). One study reported a sensitivity of 70% and specificity of 90% when a maximum SUV cutoff of 2.5 was used to identify disease-involved lymph nodes (Vag et al., 2014). In the context of biochemical recurrence, ^{11}C-choline allows for the reliable detection of sites of disease, with increasing sensitivity at higher prostate-specific antigen (PSA) levels (Krause et al., 2008). In one meta-analysis, the pooled detection rate of ^{11}C-choline PET across 16 studies of men with biochemically recurrent prostate cancer was 62.2% (95% CI, 48.9% to 74.4%) (Sathianathen et al., 2018). There are a number of mechanistically similar radiotracers to ^{11}C-choline that have been studied for prostate cancer imaging, including ^{18}F-fluorocholine, ^{18}F-fluoromethylcholine, and ^{11}C-acetate (Brogsitter et al., 2013). None of these agents, however, have gained FDA approval. Of note, ^{11}C-choline and its related radiotracers do not appear to have a role in characterizing primary prostate cancer, as uptake can be seen in areas of inflammation within the prostate, thereby providing false-positive results (Farsad et al., 2005).

The next radiotracer to be granted FDA approval for prostate cancer imaging was the synthetic amino acid ^{18}F-FACBC (also known as ^{18}F-fluciclovine). ^{18}F-FACBC functions as a substrate for the amino acid transporters LAT1 and ASCT2, which are overexpressed by multiple malignancies including prostate cancer (Oka et al., 2012). The longer half-life of ^{18}F (109.7 minutes) in comparison to ^{11}C (20.3 minutes) has allowed ^{18}F-FACBC to be made widely available to most centers in the United States. As a metabolism-based radiotracer, the diagnostic performance of ^{18}F-FACBC somewhat parallels that of ^{11}C-choline. For instance, ^{18}F-FACBC also has limited diagnostic use in primary prostate cancer, as uptake in sites of cancer is quite similar to benign prostatic hyperplasia (Turkbey et al., 2014). Additionally, in the context of preoperative staging, ^{18}F-FACBC performs similar to ^{11}C-choline; however, no direct comparison between the two radiotracers has been performed in this setting (Zarzour et al., 2017). In terms of imaging biochemical recurrence, comparative studies suggest that ^{18}F-FACBC offers slightly improved sensitivity and specificity over ^{11}C-choline across a wide range of serum PSA values (Nanni et al. 2014, 2015, 2016).

An additional class of radiotracers for prostate imaging are the prostate-specific membrane antigen (PSMA)-targeted agents. PSMA is a type II transmembrane glycoprotein that is highly expressed by prostate cancer epithelial cells (Wright et al., 1995; Sweat et al., 1998). Compounds targeting PSMA are increasingly being used throughout the world and appear poised to become the dominant means by which prostate cancer is imaged. As of yet, these agents are not FDA approved, but are nonetheless considered by many practitioners outside of the United States as a new standard of care. The majority of small-molecule PET radiotracers targeting PSMA are negatively charged urea-based small molecules that have a very high affinity for the PSMA active site (Rowe et al., 2016). Much of the early clinical work with PSMA-targeted radiotracers was carried out with ^{68}Ga-labeled agents (e.g., ^{68}Ga-PSMA-11 and ^{68}Ga-PSMA-I&T), although there is a trend toward adoption of ^{18}F-labeled compounds (e.g., ^{18}F-DCFPyL and ^{18}F-PSMA-1007) that take advantage of this radionuclide's longer half-life and superior imaging characteristics (Fig. 5.6) (Sanchez-Crespo, 2013; Gorin et al., 2016a).

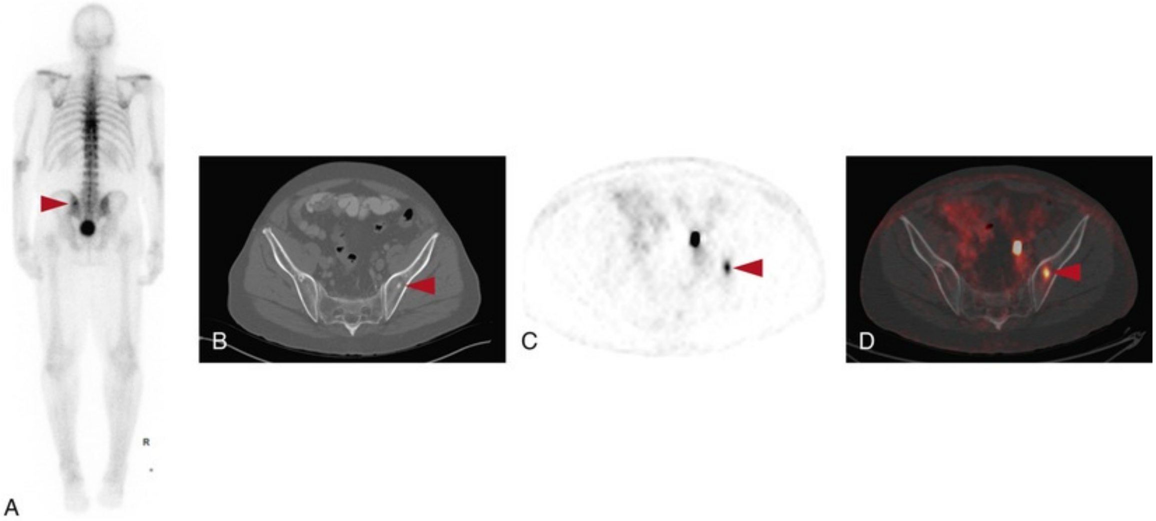

FIG. 5.6 Imaging studies of a patient with metastatic prostate cancer. (A) Posterior projection of a whole-body ^{99m}Tc-MDP planar bone scan demonstrates intense radiotracer uptake at a focus near the left sacroiliac joint *(red arrowhead).* (B) Axial, contrast-enhanced CT image through the pelvis in the same patient shows a sclerotic lesion in the left iliac that corresponds to the site of uptake on the bone scan *(red arrowhead).* (C) Axial ^{18}F-DCFPyL PSMA-targeted PET and (D) ^{18}F-DCFPyL PET/CT fusion images demonstrate intense radiotracer uptake at the same location *(red arrowheads),* corroborating the findings on bone scan and CT.

For preoperative staging, PSMA-targeted agents have the moderate-to-high sensitivity of ^{11}C-choline and ^{18}F-FACBC, but offer higher specificity (overall sensitivity 60% to 70% and specificity >90%) (Gorin et al., 2018). The detection of lesions in patients with biochemical recurrence has been the most commonly studied indication for PSMA-targeted PET radiotracers (Perera et al. 2016; von Eyben et al., 2018). In terms of patient-level detection, PSMA-targeted radiotracers have consistently been found to have higher sensitivity than choline-based radiotracers and ^{18}F-FACBC, an observation that is accentuated at lower PSA values (Afshar-Oromieh et al., 2014; Morigi et al., 2015; Schwenck et al., 2017; Alonso et al., 2018; Calais et al., 2018). As of this writing, the roles of PSMA-targeted agents in guiding metastasis-directed therapy in patients with oligometastatic prostate cancer and imaging response to therapy remain controversial (Murphy et al., 2017; Zukotynski et al., 2018). A final note regarding PSMA-targeted diagnostic radiotracers is that patients with high-volume disease and high uptake may be eligible for PSMA-targeted endoradiotherapies with β- or α-emitting agents that deliver lethal doses of radioactivity to sites of prostate cancer (Kulkarni et al., 2018).

One final class of prostate cancer–targeted radiotracers deserving of mention are those targeting the gastrin-releasing peptide receptor (GRPR), which is overexpressed in many human malignancies including prostate cancer (Ananias et al., 2009). Both agonist and antagonist peptide derivatives of bombesin bind to GRPR with high affinity, and a number of different radionuclides have been used to label bombesin derivatives, including ^{18}F, ^{68}Ga, and ^{64}Cu (Mansi et al., 2016). The GRPR antagonist ^{68}Ga-RM2 appears to have similar sensitivity for detection of sites of putative disease in biochemical recurrence as a ^{68}Ga-labeled PSMA-targeted agent (Minamimoto et al., 2016).

The increasing number of prostate cancer PET agents has the potential to cause confusion in the field, and it remains necessary to standardize the manner in which these agents are used to best take advantage of the relative merits of the various imaging agents. This level of guidance is currently absent from prostate cancer guidelines, as is how molecular imaging should be used in concert with traditional imaging techniques (Mottet et al., 2017; Cornford et al., 2017; Sanda et al., 2018a, 2018b). Further data—particularly those collected in clinical trials and well-designed prospective studies—are needed to better define the role of molecular imaging of prostate cancer.

Penile Cancer

Squamous cell carcinoma of the penis shows high levels of ^{18}F-FDG uptake (Ottenhof and Vegt, 2017). One application of ^{18}F-FDG imaging in patients with penile cancer is inguinal lymph node staging. More specifically, ^{18}F-FDG PET offers a reliable method for confirming the presence of metastatic disease and determining the relative extent of nodal involvement in patients with palpable inguinal lymph nodes. A meta-analysis by Saeghi et al. reported a sensitivity of 96.4% for detecting nodal metastases among patients with palpable groin nodes (95% CI, 81.7% to 99.9%) (Sadeghi et al., 2012). Thus, in this high-risk population, ^{18}F-FDG is useful for assessing extent of disease and steering patients with large-volume nodal involvement toward neoadjuvant chemotherapy. In contrast, the utility of ^{18}F-FDG PET for primary tumor staging and the evaluation of patients with nonpalpable inguinal lymph nodes is somewhat limited. More specifically, in the meta-analysis by Saeghi et al. the pooled sensitivity of ^{18}F-FDG PET for detecting otherwise clinically occult lymph node metastases was only 56.5% (95% CI, 34.5% to 76.8%) (Sadeghi et al., 2012). It is worth noting that although ^{18}F-FDG PET can be used to detect distant sites of penile cancer, the literature on this topic is somewhat scarce, and little is known regarding the clinical benefits of this practice (Ottenhof and Vegt, 2017).

Testis Cancer

Molecular imaging with ^{18}F-FDG PET has had a long-standing application in the evaluation of patients with metastatic tesitular seminoma. Current guidelines from the European Association of Urology endorse the use of this imaging modality for men with a residual mass after treatment with chemotherapy (Albers et al., 2015). Using ^{18}F-FDG PET in this manner helps differentiate fibrosis from residual active tumor. A meta-analysis that included data from 9 studies found that ^{18}F-FDG PET had a pooled sensitivity of 78% (95% CI, 67% to 87%) and a specificity of 86% (95% CI, 81% to 89%) for detecting residual tumor after chemotherapy (Treglia et al., 2014). For patients with nonseminomatous germ cell tumors, ^{18}F-FDG PET imaging is not indicated, as there appears to be no clinical benefit for PET in the detection of viable tumor over the combination of CT and serum markers (Oechsle et al., 2008). The development of a PET radiotracer capable of detecting residual tumor in patients with nonseminomatous germ cell tumors is a critical need, as the current standard of care is retroperitoneal lymph node dissection for postchemotherapy tumors greater than 1 cm in diameter (Albers et al., 2015).

Key Points

- Molecular imaging of cancer is most commonly performed using the PET radiotracer 2-deoxy-2-[^{18}F]fluoro-D-glucose (^{18}F-FDG).
- A number of genitourinary malignancies can be successfully imaged with ^{18}F-FDG PET albeit with varying degrees of clinical utility beyond conventional anatomic imaging techniques.
- Because ^{18}F-FDG is excreted in the urine, imaging with this radiotracer is typically performed to detect distant sites of disease.
- ^{18}F-FDG has little role in imaging prostate cancer, and a number of other radiotracers have been developed for this purpose.

- Radiotracers targeting PSMA are the most promising class of agents for prostate cancer imaging and in many parts of the world have become the new standard of care for imaging this malignancy.
- One of the most well established indications for ^{18}F-FDG PET imaging is in the detection of residual seminomatous germ cell tumors after chemotherapy.

Assessment of Urologic and Surgical Outcomes

David F. Penson MD, MPH, Mark D. Tyson MD, MPH

Over the past 25 years, there has been increased focus on "outcomes research" in urology. Unfortunately, outcomes research is an umbrella term without consistent definition. Jefford et al. noted that outcomes research tends to describe the effectiveness of public health interventions and health services on patient outcomes (Jefford et al., 2003). Others, however, have described it differently. **The US Agency for Healthcare Research and Quality (AHRQ) defined outcomes research as "research [that] seeks to understand the end results of particular health care practices and interventions.** End results include effects that people experience and care about, such as change in the ability to function. In particular, for individuals with chronic conditions—where cure is not always possible—end results include quality of life as well as mortality. By linking the care that people get to the outcomes they experience, outcomes research has become the key to developing better ways to monitor and improve the quality of care" (AHRQ, 2000). People with urologic conditions, however, care about any number of end results, which underscores the difficulty of accurately defining "outcomes research" in urology. Some endpoints that matter in urology include quality of life, clinical effectiveness, cost, quality of care, patient preferences, appropriateness, access, and health status, just to name a few (Jefford et al., 2003).

Some might use the terms *outcomes research* and *health services research* interchangeably. This is not entirely unreasonable, as health services research constitutes a major portion of what urologists think of when they are referring to outcomes research. Health services research has been defined as "the multidisciplinary field of scientific investigation that studies how social factors, financing systems, organizational structures and processes, health technologies, and personal behaviors affect access to health care, the quality and cost of health care, and ultimately our health and well-being" (Lohr and Steinwachs, 2002).

Although this definition captures much of what urologists think of when speaking of outcomes research, it fails to capture the often clinical nature of the research. **To this end, urologic outcomes research not only includes health services research—it also includes clinical epidemiology, comparative effectiveness research, and, to some degree, traditional clinical trials research.**

Establishing a Conceptual Framework for Assessing the Effectiveness of Treatment and Improving Care in Urology

Implicit in the name "outcomes research" is a focus on improving the end results of urologic interventions. This has led to an increased focus on improvement in the quality of care delivered. The Institute of Medicine (IOM) has defined quality of care as "the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge" (IOM, 2001). The IOM notes that quality can be affected by various elements of care including access, clinical effectiveness, integration of services such as care coordination and continuity, cultural competence, and comprehensiveness (IOM, 2001). As such, there is a pressing need for a conceptual model to guide quality improvement and optimize end results.

The most commonly accepted framework through which quality is measured is the model proposed by Avedis Donabedian (Donabedian, 1966, 1978, 1988). **The Donabedian model is a conceptual framework for examining health services and assessing quality in health care. The model consists of three dimensions in which the quality of care can be measured: structure, process, and outcomes.** Importantly, it is possible (and desirable) to measure specific elements of each of these dimensions to assess the overall quality of care.

***Structure* consists of the factors that affect the context in which the care is delivered.** Examples of measurable elements of structure include procedure volume, subspecialty training, nurse-to-bed ratios, or the presence of specific amenities such as "closed" intensive care units or certain types of technology and equipment (Brook et al., 1996; Donabedian, 1986; Luft et al., 1987). Structural quality of care measures are usually easily and inexpensively obtained from administrative databases and other publicly available sources (Donabedian, 1996; Liu et al., 2006). Although structural measures may be more relevant in complex health care systems, they often fail to capture the quality of care actually delivered at the provider level and tend to be nonmodifiable. That being said, there is little doubt that they influence the quality of care and clinically relevant endpoints, so they need to be considered.

***Process* refers to specific activities carried out by health care professionals and health care systems to deliver services** (Brook and Appel, 1973). Examples of measurable processes include the appropriate use of radiographic and laboratory testing, assessment of types of medication prescribed (i.e., the use of antibiotics before a procedure or deep venous thrombosis prophylaxis), specific technical processes performed in the completion of a surgical procedure, and so on. There is enthusiasm for process measures because of a clearly established link between process measures and improved outcomes where the evidence is robust (e.g., preoperative heparin for DVT prophylaxis in major cancer cases) (Guyatt et al., 2012). An additional advantage to process measures is that quality problems can usually be detected long before demonstrable outcome differences become evident (Mant and Hicks, 1995, 1996). Evidence-based practice guidelines, like those generated by the American Urological Association (AUA) or the European Association of Urology (EAU), have greatly facilitated the development of quality-of-care process measures. For example, the AUA guidelines strongly recommend the use of 24 to 36 months of androgen deprivation therapy as an adjunct to external beam radiotherapy in localized prostate cancer (Sanda et al, 2018a; 2018b). This, in turn, has been used as a quality-of-care process measure in a number of programs, including Medicare's physician quality reporting system and by numerous private payors (Spencer et al., 2003a, 2003b). Donabedian suggested that measurement of the processes of care may be the most reflective measurement of overall quality of care because process contains all of the elements of health care delivery (Donabedian, 1980). Compared with outcome measures, process measures are easier and less costly to measure, and, unlike outcome measures, are less influenced by case-mix or risk adjustment when carefully specified (Mant, 2001).

***Outcomes* measures refer to the effects of health care on patients or populations.** Whereas structural measures focus on the infrastructure of health care delivery and process measures focus on how health care is delivered, outcome measures focus on the effect of health care on patients, which many feel is the most important indicator of quality of care. A few examples of commonly used outcomes measures include mortality rates, length of stay, readmission rates, patient satisfaction, quality of life, cost-effectiveness, and utilization. Although some have advocated that outcomes should be the primary (and perhaps only) focus of quality improvement efforts (McAuliffe, 1979), others have noted problems with using these measures, primarily resulting from confounding by patient-level factors such as age and comorbidity (Lilford et al., 2007; Rademakers et al., 2011). **There is certainly a pressing need for proper risk adjustment when assessing outcomes.** If studies do not include proper case-mix adjustment, they might find that providers who treat high-risk patients have poorer outcomes, not necessarily because of poorer quality of care, but because of underlying differences in patient populations. This, in turn, could create an economic disincentive to treat these patients and negatively affect their health.

Long-Term Disease Outcomes That Are Commonly Assessed in Urology

Although structure and process contribute to overall quality of care, patients and urologists tend to focus mostly on outcomes, as having “good” clinical results and/or stable or improved day-to-day health is usually the primary goal of the treatment of any urologic condition. In many regards, this is why the term *outcomes research* has become so prevalent. That being said, there are a myriad of outcomes that can be studied in urologic research. It is important to understand the strengths and weaknesses of the various types of outcomes if one is to undertake research in this space. Surgeons tend to be most concerned with morbidity and mortality, as these are the “hardest” endpoints and, at least in theory, are easiest to assess. Patients and other stakeholders are also interested in these endpoints but may have additional focus on other “softer” endpoints, including patient-reported outcomes (such as symptoms and bother), economic endpoints, and satisfaction with care. The variety of outcomes that can be assessed in urologic research are discussed in the following sections with attention to how to measure these endpoints and some of the strengths and weaknesses of each.

Overall Mortality

Mortality refers to “death” and, in many regards, it is the most objective of all endpoints one can measure. After all, there is usually no argument regarding whether or not a patient is alive or dead. **Overall (or all-cause) mortality is a key endpoint in epidemiology that can be assessed in larger population-based studies in the United States by querying the National Death Index (NDI), which is maintained by the National Center for Health Statistics (NCHS) within the Centers for Disease Control and Prevention (CDC)** (CDC, 2019). Data are obtained from the vital statistics office from each of the 50 states and are then stored centrally. The NDI is updated annually, and the information contained within the dataset tends to lag behind 1 calendar year. Researchers are requested to submit as much identifying information as possible, including the subject's name, Social Security number, date of birth, race, sex, marital status, state of residence, and state of birth. If the subject has died, the

NDI will provide the location and date of death and the corresponding death certificate number. The NDI can also provide the cause of death as listed on the death certificate. Numerous studies have demonstrated that the NDI has an accuracy rate of 96% or higher (Boyle and Decouflé, 1980; Stampfer et al., 1984). Unfortunately, the NDI only contains data on deaths that occurred after 1979 in the United States. For information on deaths that occurred before this time in the United States, the researcher can query the Social Security Administration (SSA), which maintains a mechanism for researchers to determine vital status (SSA, n.d.). The SSA dataset is less accurate than the NDI; researchers were only able to document an 83% accuracy rate (Boyle and Decouflé, 1980; Curb et al., 1985). One last option that may also contain international options involves the use of records from the various credit reporting agencies (Equifax, Experian, and TransUnion) or other Internet databases to ascertain vital status (Sesso et al., 2000). This approach, however, may not be as comprehensive as the NDI.

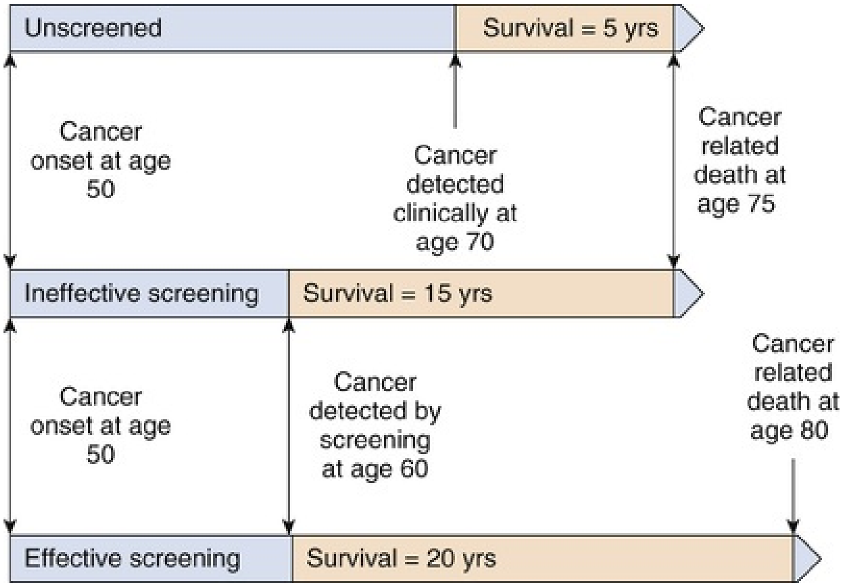
Once ascertained, mortality (or its reciprocal, survival) can be assessed as a simple count, a ratio, a proportion, or a rate. For most clinical studies in urology, the use of a proportion or a rate is most appropriate. For example, if one were comparing overall mortality between two arms of a clinical trial, one could simply calculate the proportion of participants in each study arm who died (or were alive if the researchers wished to focus on survival) over the total number of study participants in each arm. Although this simple approach has face validity, it fails to account for the element of time, which is usually of significance. To this end, the preferred approach is usually to calculate a mortality *rate*, defined as the proportion of dying in a population *over a specified period* (Last, 2001). Expanding on the earlier example, assume the randomized clinical trial is comparing second- or third-line treatments for castrate-resistant metastatic prostate cancer. In this setting, one would likely expect all of the study participants to die within the study period. To this end, comparing mortality rates at the conclusion of the study would be less meaningful. Researchers, therefore, might compare 1-, 2-, and 5-year mortality rates between two treatments in a randomized clinical trial to assess the comparative effectiveness of each therapy.

Comparing mortality (or its reciprocal, survival) endpoints over time is facilitated by using time-to-event analyses (commonly referred to as *survival analyses,* although any binary endpoint can be used with these methods) (Feinstein, 2002). **One of the unique advantages of survival analyses is that**

they allow researchers to account for situations in which there is varying or loss to follow-up among subjects. For example, assume that a researcher is analyzing clinical trial data at the conclusion of a study. The majority of the participants were followed for 3 years, but a significant proportion were only followed for 1 to 2 years, and others were lost to follow-up well before the end of the 3-year study. Survival or time-to-event analyses allow researchers to include all participants, even if they do not have complete data. This is accomplished through censoring of participants (Feinstein, 1985). Effectively, if we know that a study participant did not experience the outcome of interest up to the point when there is no additional follow-up (either resulting from the participant being lost to follow-up or the study ending) or another endpoint occurring making it impossible for the outcome of interest to occur (such as a patient dying of an unrelated heart attack before experiencing a disease recurrence), the patient is considered to have "survived" up to that point and is then censored. The use of censoring is critical to the construction of Kaplan-Meier curves, which graphically illustrate survival (time-to-event) analyses and provide survival estimates at various timepoints during a study that incorporate both clinical outcome and censoring events (Rich et al., 2010).

Although overall mortality is a relatively easy endpoint to assess in individual patients and is not really subject to interpretation bias, it does not mean that studies that use this endpoint may not be susceptible to various forms of bias, often related to study design. Two examples of this are lead-time and length-time bias. **Lead-time bias is most likely to occur in studies of screening tests and other novel diagnostic modalities.** Lead time is defined as the period from detection of disease (which is intimately related to novel screening and detection modalities) and the disease's clinical presentation and diagnosis (Feinstein, 1987; Gordis, 2008). The goal of a screening test is usually to allow clinicians to detect a condition earlier in the disease course. In the absence of a screening test, the disease would not be diagnosed until symptoms appeared. **This ability to detect the disease earlier may give the appearance that survival is prolonged, despite the fact that it is not. Rather, it is simply identified earlier.** This is represented graphically in Fig. 6.1. There are numerous examples of lead-time bias in urology, although the best one may be kidney cancer. Over the past 30 years, the incidence rate of kidney cancer has doubled (presumably caused by increased use of abdominal computed tomography (CT) scanning, which results in increased detection of asymptomatic renal masses). Population-based studies have shown that the 5-year survival rate in kidney cancer has increased from

50% to 75%. During the same time, however, the mortality rate from kidney cancer has remained stable, implying that the survival benefit is likely caused by lead-time bias (Welch and Fisher, 2015). Similarly, claims of improved survival as a result of prostate-specific antigen (PSA) testing in prostate cancer (Bokhorst et al., 2015) have been attributed to lead-time bias by some researchers (Carlsson and Albertsen, 2015).



Unscreened
Survival = 5 yrs
Cancer onset at age 50
Cancer detected clinically at age 70
Cancer related death at age 75
Ineffective screening
Survival = 15 yrs
Cancer onset at age 50
Cancer detected by screening at age 60
Cancer related death at age 80
Effective screening
Survival = 20 yrs

FIG. 6.1 Lead-time bias related to screening. In the unscreened patient, survival is 5 years. In the screened patient, the cancer is detected 10 years before it would have presented clinically. In the setting of an ineffective screening intervention, survival appears longer (15 years), but in reality, the 10-year survival difference is caused by lead-time bias. Conversely, in the setting of effective screening, the cancer is still detected 10 years before it would have presented clinically, but the patient's survival is prolonged by an additional 5 years, making the overall survival 20 years total.

Length-time bias can also give the appearance of improved survival as a result of screening when, in fact, no advantage actually exists (Feinstein, 1985; Gordis, 2008; Last, 2001). Consider the example of prostate cancer. Each PSA screening test occurs at a single point in time that is relatively random in the disease course. It is known that higher-grade, more aggressive cancers have a faster disease course, and lower-grade more indolent cancers have a slower disease course (D'Amico et al., 1998). **As illustrated in Fig. 6.2, slower-growing tumors usually have a much longer asymptomatic phase, and, to this end, they are more likely to be detected by screening tests than fast-**

growing tumors. Assuming that these slower-growing tumors are less likely to be fatal, it may appear that patients whose tumors are detected by screening have a longer survival, even though there is no true survival benefit to catching the tumor earlier. Lead- and length-time bias underscore the observation that even the most objective endpoint in urology, mortality, may be subject to problems in interpretation, and, as such, researchers must be aware of this when comparing outcomes after treatment of urologic diseases.

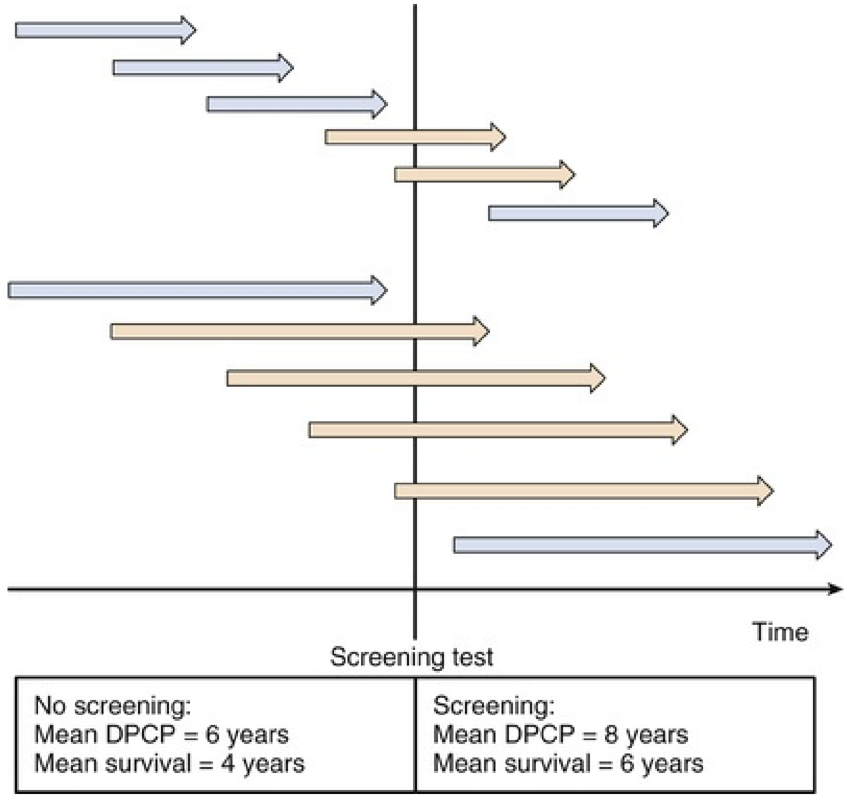


FIG. 6.2 Length-time bias in screening. Cancers can have varying degrees of clinical growth. Those that are slower growing and less aggressive will have longer detectable preclinical periods (DPCP), and those that are faster growing and more aggressive will have shorter DPCPs. It is also safe to assume that the slower growing tumors would have a longer period from clinical detection to cancer-related death (assuming the patient does not succumb to a non–cancer-related mortality beforehand). Each *arrow* represents a single patient with onset of cancer on the left and clinical presentation in the absence of screening on the right. *Red arrows* represent cases that would be detected with a screening intervention, and *blue arrows* represent cases that would not be detected by screening. Screening appears to prolong survival because screening detects more slower growing, less-aggressive cancers.

Disease-Specific Mortality

Although overall mortality is the “hardest” endpoint one can measure in urology, it is also the crudest in many regards. It fails to account for other intercurrent illnesses that may result in mortality. It is also not always the most germane endpoint, particularly in benign diseases or those with relatively low mortality rates. To this end, disease-specific mortality is often used in urology to assess the effectiveness of treatment.

Disease-specific mortality is defined as deaths attributed directly to the disease under study (Gordis, 2008). Although many urologists believe that this is easy to define, it is actually considerably more complicated than one might appreciate, particularly in the setting of “benign” disease. Many urologic conditions are primarily treated via a surgical approach, yet if there is a mortality event within the immediate postoperative period, one's immediate inclination is not to attribute the death to the urologic condition. That being said, one could make a strong argument that the mortality event is directly related to the urologic disease and its treatment and should be considered a disease-specific mortality event. To test this, Welch and Black used data from the Surveillance, Epidemiology, and End Results (SEER) database from 1994 to 1998 and noted that 75% of deaths reported within 1 month of surgery for prostate cancer were attributed to a cause other than prostate cancer (Welch and Black, 2002). Had these deaths been attributed to prostate cancer, disease-specific mortality would be increased by 1% to 2%, in a condition that already has a relatively low mortality rate (Hoffman et al., 2013). Clearly, these data are taken from early in the PSA era before the introduction of robotic surgery, but they illustrate some of the nuances of defining disease-specific mortality, even when all of the data are properly collected and available.

This extends to medical treatment as well. Consider the patient who is on long-term androgen deprivation therapy (ADT) for metastatic prostate cancer. Numerous studies have documented an increased risk for cardiovascular disease and death presumably related to changes in the hormonal milieu related to ADT (Nguyen et al., 2015; Keating et al., 2006; Nguyen et al., 2011). If this patient dies of a cardiac event, is this related to the treatment of his prostate cancer? By extension, could he have avoided this event if he never had prostate cancer and did not receive ADT? Similarly, this same patient could have been admitted to the hospital with pneumonia and ultimately experience overwhelming sepsis, vascular collapse, and cardiac arrest. One could argue that metastatic prostate cancer caused the patient to become immobile and may have contributed to the development of pneumonia, which in turn, led to sepsis and death. Alternatively, one could argue that older patients are prone to pneumonia and that the death had nothing to do with the underlying prostate cancer, as he would have died of infection regardless of malignancy. To this end, disease-specific mortality is subject to interpretation and may be prone to "attribution bias" (Feinstein, 1987; Sackett et al., 1991).

Attribution bias is the greatest limitation of using disease-specific mortality as an outcome. When patients are diagnosed with an underlying urologic malignancy, this is usually well-documented in the medical record, even if the patient is hospitalized for unrelated reasons. If the patient expires during the hospital admission, the malignancy is often recorded on the death certificate, which sometimes results in the cause of death being attributed to the cancer, even if the death really is not related (Mackenbach et al., 1997; Maudsley and Williams, 1994).

This has been documented in various urologic cancers. In prostate cancer, for example, there have been a number of studies that have examined the ability of clinicians to accurately ascribe cause of death on the death certificate. Albertsen et al. abstracted the inpatient medical records of 201 men who died with prostate cancer in Connecticut in either 1985 or 1995 (Albertsen et al., 2000). The researchers then performed a medical record review and independently assigned cause of death, which was then compared with the cause of death recorded on the death certificate. Although agreement was fairly high (87%), there were still discrepancies in nearly 1 of 10 cases, indicating that although the risk for attribution bias is not overwhelming, the cause of death is still open to interpretation at least 10% of the time. Penson et al. and Hoffman et al. noted similar findings in their review of subjects from Seattle and New Mexico, respectively (Penson et al., 2001; Hoffman et al., 2003).

Attribution bias is not limited to prostate cancer. Chow and Devesa studied a population of deceased patients with urinary tract tumors identified through the Surveillance, Epidemiology and End Results (SEER) program (Chow and Devesa, 1996). Tumors were classified as arising from the bladder, kidney, renal pelvis, or other site in the urologic tract. Cause of death in a significant number of these cases was ascribed to nonurologic conditions and varied by site of the primary cancer (48% of bladder, 28% of kidney, 37% of renal pelvis, and 38% of other urinary site cases). Not surprisingly, the more advanced the disease stage at diagnosis, the more likely the cause of death was ascribed to cancer. However, site of the primary tumor did affect whether or not the cause of death was related to cancer. Comparing similar-stage renal pelvic tumors to kidney tumors, 5.5% of renal pelvic tumor cases were recorded in the death certificate as death caused by cancer compared with 33.7% in kidney cancer cases. It is worth noting that all of these studies tend to focus on in-hospital deaths only. It is even more difficult to determine cause of death for individuals who die at home or in a nursing facility**. In summary, although disease-specific mortality rates are commonly used in many urologic studies and are usually relatively reliable, there may be some attribution bias and misclassification that can affect the conclusions.**

Other Binary “Survival” Outcomes

Effectively, any definable binary outcome can be converted into a survival endpoint and assessed using Kaplan-Meier curves and proportional hazards analysis (Rich et al., 2010; Feinstein et al., 1990). Examples of these types of endpoints include metastatic-free survival, radiologic progression-free survival, symptom-free survival, and biochemical-free survival, just to name a few. Binary nonmortality endpoints are commonly used in benign conditions (Tasian et al., 2017) and in malignancies like prostate cancer (Jhaveri et al., 1999; Prada et al., 2012), where mortality events may be rare or take a long-time to occur. **Because each urologic disease is somewhat unique, clinically relevant outcomes of interest vary from condition to condition.** It is important to recognize that some clinical outcomes are easier to measure and more objective than others. As such, many clinical endpoints are subject to an array of biases that may affect their validity. For example, results of urodynamic evaluation have been used as an endpoint in studies of urinary incontinence, but studies have shown that stress or urge incontinence cannot always be reproduced during urodynamics (Nygaard, 2004). Furthermore, even if incontinence is noted on urodynamics, there is no general agreement concerning how to define what degree of leakage is required for a patient to be considered incontinent. Some have suggested that patient-reported outcomes, such as pad use or symptom scores, should be used as endpoints (Carmel et al., 2016), but these are far less “objective” than radiologic tests or serum assays commonly used in other conditions (Naughton et al., 2004).

Proxy Endpoints

Although mortality endpoints represent the “hardest” outcomes we can measure, they often can take many years to occur. Furthermore, mortality may be almost irrelevant in benign conditions, such as incontinence or stone disease. To this end, there is often a need for other outcomes to assess the effectiveness of therapies for urologic conditions. These alternate outcomes may be clinically relevant or may be proxy endpoints for survival. **Prentice** (1989) **defined the four requirements for a valid surrogate end point as: (1) treatment is associated with the true end point (overall or disease-specific survival); (2) treatment is also associated with the surrogate end point; (3) the surrogate end point is associated with the true end point; and (4) the full effect of the treatment on the true end point is explained by the surrogate end point. There are few proxy endpoints for mortality in urology that meet all four criteria.**

Disease Progression/Recurrence

Progression-free survival is a common proxy endpoint in urologic oncology studies. Although progression is often easily defined in clinical practice, there is a need for more standardized definitions of radiologic change in tumor burden if this endpoint is to be used in research settings. Responding to this need, the World Health Organization (WHO) first introduced a set of radiologic tumor response criteria in 1981 (Miller et al., 1981). Over time, researchers modified the criteria for individual studies, which lead to confusion and studies of the same drugs with conflicting results (Baar and Tannock, 1989). This lead the European Organization for Research and Treatment of Cancer, the US National Cancer Institute, and the National Cancer Institute of Canada to convene an international working group to standardize and simplify tumor response criteria. This working group developed the RECIST criteria (Response Evaluation Criteria In Solid Tumors) in 2000 (Therasse et al., 2000). These original criteria defined the minimum size of measurable lesions, suggested guidelines on how many lesions to follow (up to ten, five per organ site) and established standardized unidimensional measures of overall tumor burden. After the original RECIST criteria had been used in the field for a number of years, several limitations of the criteria were noted including: (1) RECIST's limited ability to measure disease progression (the original RECIST criteria were focused on tumor response to therapy exclusively); (2) RECIST's need to incorporate novel imaging technologies such as magnetic resonance imaging and positron emission tomography into the criteria; (3) RECIST's inability to incorporate lymph node involvement into the criteria (as the original RECIST were focused primarily on organ site involvement; and (4) RECIST's inability to assess response to targeted noncytotoxic drugs. In response to this, the working group issued a new set of guidelines, RECIST version 1.1 (Eisenhauer et al., 2009).

RECIST 1.1 defines a measurable lesion as having a unidimensional size of 10 mm or larger on CT scan, 20 mm on chest radiograph, or 10 mm on clinical examination (measured with calipers). For a lymph node to be considered pathologically enlarged and measurable, it must be at least 15 mm in the short axis on CT scan. RECIST 1.1 advises against the use of ultrasonography to assess lesion size. It also advises against the use of tumor markers *alone* to assess tumor response, although the RECIST guidelines specifically mention the PSA response in advanced prostate cancer, as defined by the Prostate Cancer Clinical Trials Working Group (Scher et al., 2016) as a tumor marker that could be used in combination with the RECIST criteria.

RECIST 1.1 directs researchers to document at least one and up to five measurable lesions as “target lesions” to be measured at baseline and followed for the course of any study. The largest lesions should be selected as target lesions and should be selected in a way that they are both representative of all involved organs and should lend themselves to repeated measurement. The sum of the diameters of all the target lesions is measured at baseline and is then followed during the study to assess tumor response or progression. The exact criteria to define complete and partial response, stable disease, and progressive disease are presented in Table 6.1. These definitions can now be used to calculate outcomes including radiologic progression-free survival, duration of response, and overall response rate, just to name a few.

TABLE 6.1

RECIST Criteria

EVALUATION OF TARGET LESIONS	
Complete response (CR)	Disappearance of all target lesions. Any pathologic lymph nodes (whether target or nontarget) must have a reduction in short axis to <10 mm
Partial response (PR)	At least a 30% decrease in the sum of diameters of target lesions, taking as reference the baseline sum diameters.
Progressive	At least a 20% increase in the sum of diameters of target lesions, taking as

disease (PD)	a reference the smallest sum on study (this includes the baseline sum if this is the smallest on study). In addition to the relative increase of 20%, the sum must also demonstrate an absolute increase of at least 5 mm. The appearance of new lesions is considered progression.
Stable disease (SD)	Neither sufficient shrinkage to qualify for PR nor sufficient increase to qualify for PD, taking as reference the smallest sum diameters while on study.
EVALUATION OF NONTARGET LESIONS	
Complete response (CR)	Disappearance of all nontarget lesions and normalization of any tumor marker levels. All lymph nodes must be <10 mm in size along short axis.
Non-CR/Non-PD	Persistence of one or more nontarget lesion(s) and/or maintenance of tumor marker level above normal limits.
Progressive disease (PD)	Unequivocal progression of existing nontarget lesions and/or the appearance of new lesions.

From Eisenhauer EA, Therasse P, Bogaerts J, et al. New response evaluation criteria in solid tumours: revised RECIST guideline (version 1.1). *Eur J Cancer* 45(2):228–247, 2009.

Although the RECIST criteria standardize the definition of radiologic disease progression, they do not eliminate the risk for detection bias**. Detection bias occurs when one group of patients in a study is more likely to have a progression detected than the other, perhaps as a result of increased imaging or closer clinical follow-up** (Feinstein, 1987)**. Although this is less likely to occur in the setting of a prospective clinical trial (where follow-up is usually dictated by study protocol and should be similar between the two arms of the study), it is not uncommon in observational and/or retrospective studies and must be considered when reviewing the literature** (Feinstein, 1985).

Another important consideration is variation in radiologist interpretation of imaging studies. Take the example of renal calculus disease, where stone burden is relatively easily assessed with computerized tomography. There can be differences in study interpretation among radiologists and even by the same radiologist reading the study at a different date (interobserver and intraobserver variability, respectively). To quantify the degree of variability, Jewett et al had three different radiologists review post–shock wave lithotripsy CT scans of 58 patients (Jewett et al., 1992). The reviewers disagreed with each other 24% of the time and with themselves 16% of the time. This study clearly documents that radiographic outcomes after stone treatment are far less objective than one might imagine. There is no reason to believe that this is not true for other urologic conditions in which radiographic imaging is used to define outcomes. This is why many prospective clinical trials will have central review of imaging (or pathology for that matter).

Receipt of Secondary Therapy

Rates of secondary therapy are often reported as an outcome in studies of malignant urologic conditions (Grossfeld et al., 2002; Lu-Yao et al., 1996) and nonmalignant urologic conditions (McConnell et al., 2003). Although receipt of secondary therapy may seem quite easy to measure and objective at first glance, it is, in fact, subject to considerable bias. For example, consider secondary therapies for prostate cancer. If a patient undergoes surgery and is found to have high-risk disease, he may receive additional radiotherapy or hormonal ablation therapy (Thompson et al., 2006). Is this considered a secondary therapy or an adjuvant to primary treatment? **Furthermore, secondary therapies are often initiated for subjective reasons. Men who experience a biochemical recurrence after radical prostatectomy will often elect to receive hormone ablation or radiotherapy, although this “recurrence” may not be clinically meaningful** (Freedland et al., 2005). **Some researchers have referred to this as “discretionary” treatment** (Shahinian et al., 2010). Although all therapies are presumably given at the discretion of the provider, it is also assumed that the treatments given are medically necessary. In situations in which this is not clear, subjectivity and bias can come into play.

Commonly Assessed Short-Term Outcomes

Assessing Surgical Complications

One of the most commonly studied outcomes in urology is postoperative complications. A complication can be broadly defined as any occurrence that deviates from the "normal" or expected course of events after surgery. That being said, there are differing degrees of complications, and some complications may be more unexpected than others. There have been a number of standardized systems proposed for classifying surgical complications that can be used in both clinical and research settings.

Common Terminology Criteria for Adverse Events

The Common Terminology Criteria for Adverse Events (CTCAE) system was developed in the early 1980s to classify complications after treatment for cancer. It is now broadly accepted and used by the National Cancer Institute cooperative groups and industry to assess complications in clinical trials. Now in its fifth iteration, Common Terminology Criteria for Adverse Events (CTCAE) Version 5.0 uses a grading scale for each of the various organ systems from 1 to 5 to classify complications, from "mild" to "death" (U.S. Department of Health and Human Services, 2017) (Table 6.2). The system is relatively simple, which makes it well-suited for trials involving novel agents and therapies in which there is an increased risk for unexpectedly serious or life-threatening complications. That being said, it is a relatively unrefined grading system that is not specific to surgical treatment and does not have the granularity required for many comparative effectiveness studies.

TABLE 6.2

CTCAE System for Classification of Surgical and Medical Procedures

1	Asymptomatic or mild symptoms; clinical or diagnostic observations only; intervention not required
2	Moderate; minimal, local, or noninvasive intervention indicated; limiting age-appropriate instrumental ADLs
3	Severe or medically significant but not immediately life-threatening; hospitalization

	or prolongation of existing hospitalization indicated; disabling; limiting self-care ADLs
4	Life-threatening consequences; urgent intervention indicated
5	Death

ADLs, Activities of daily living; *CTCAE,* Common Terminology Criteria for Adverse Events.

Clavien-Dindo System of Classifying Complications

In 1992, Clavien et al. proposed a new grading system for the severity of complications specifically related to surgical treatments. This new framework was centered around the risk and invasiveness of the therapy required to address or treat the complication (Table 6.3). They posited that by focusing on the therapy required to treat the unexpected event, the system minimized the influence of subjective interpretation of the severity of the complication. In 2004, Dindo et al. proposed modifications of the original system, expanding it from 4 to 5 grades that contained a total of 7 possible strata (Dindo et al., 2004). This modification allowed more precise classification by capturing whether the intervention in response to the complication required the use of general anesthesia for administration and whether the complication itself led to organ failure and/or admission to an intensive care unit. This reporting system, known as the Clavien-Dindo classification system, has been extensively validated and evaluated for interobserver variability (Clavien et al., 2009).

TABLE 6.3

Clavien-Dindo Classification of Complications

GRADE	DEFINITION	EXAMPLE
I	Any deviation from the normal postoperative course without the need for pharmacologic treatment or surgical, endoscopic, or radiologic intervention. Allowed therapeutic regimens include antiemetics, antipyretics, analgesics, diuretics, and so on. This grade also includes wound infections opened at the bedside.	Prolonged postoperative ileus after cystectomy managed with observation and normal IV fluids (not total parental nutrition).
II	Any deviation from the normal postoperative course requiring pharmacologic treatment with medications/pharmacologic interventions other than those allowed for grade I	Perioperative bleeding after nephrectomy requiring blood transfusion and continued monitoring of serum

	complications.	hemoglobin without admission to an intensive care unit.
IIIa	Any deviation from the normal postoperative course requiring surgical, endoscopic, or radiologic intervention WITHOUT the need for general anesthesia.	Pelvic fluid collection after prostatectomy requiring placement of percutaneous drain in interventional radiology with local anesthesia and mild sedation only.
IIIb	Any deviation from the normal postoperative course requiring surgical, endoscopic, or radiologic intervention WITH the need for general anesthesia.	Any unplanned takeback to the operating room for any reason that requires general anesthesia.
IVa	Any life-threatening complication (including central nervous system [CNS] complications)[a] that require intermediate care/intensive care unit management. IVa is defined a single-organ dysfunction only.	Patient has an isolated myocardial infarction immediately after percutaneous nephrolithotomy that requires transfer to cardiac intensive care unit for observation and pharmacologic management.
IVb	Any life-threatening complication (including CNS complications)[a] that require intermediate care/intensive care unit management. IVb is defined a multi-organ dysfunction only.	Patient has myocardial infarction and hypotension after partial nephrectomy that results in renal failure and acute respiratory distress syndrome and is transferred to ICU for intubation, pressors, and dialysis.
V	Death of a patient.	Postoperative mortality of any type.

[a] Brain hemorrhage, ischemic stroke, subarachnoid bleeding. This excludes transient ischemic attacks (TIAs).

Modified from Dindo D, Demartines N, Clavien PA. Classification of surgical complications: a new proposal with evaluation in a cohort of 6336 patients and results of a survey, *Ann Surg* 240(2):205–213, 2004.

Although the Clavien-Dindo system, as it has come to be known, has been widely used and accepted in the past decade, it still has a number of limitations that should be acknowledged. **First, there is still an element of subjective interpretation of the severity of complications, which may introduce**

variability within the grading assignments. For example, urologists may grade a recognized rectal injury during a radical prostatectomy differently: grade 1 for prolonged hospital stay versus grade 3 for intraoperative repair under general anesthesia (Morgan et al., 2009). **Second, some interventions may be performed under local anesthesia at one institution but general anesthesia at another, which introduces interrater variability within grades 3 and 4** (Rassweiler et al., 2012)**. Third, this system may fail to capture the increased severity when two complications of the same grade occur in the same patient. Lastly, two patients with the same complication may be managed differently at two separate institutions (e.g., IVC filter vs. heparinization alone for DVT).**

Assessing Risk for Surgical Complications

A goal of many quality improvement initiatives is to identify patients at greater risk for surgical complications so one can potentially make perioperative interventions to reduce complication rates. To do this, it is critical to understand risk factors for postoperative complications. Although specific procedures carry specific risk factors, there are several clinical characteristics that apply across all surgical procedures and can predict the risk for surgical complications. These include functional status, comorbidity, and frailty (Fried et al., 2001; 2004).

Functional Status

Functional status is defined as an individual's ability to perform normal daily activities required to meet basic needs, fulfill usual roles, and maintain health and well-being (Leidy, 1994a; 1994b; Wilson and Cleary, 1995). Effectively, functional status reflects an individual's ability to perform routine activities of daily living (ADLs). The six essential ADLs include the ability to eat independently; dress; walk or transfer from one place to another; bathe; use the bathroom for toileting; and maintain good continence (Edemekong and Levy, 2019). There are a number of established tools available for determining functional status by assessing a patient's ability to perform ADLs (Buurman et al., 2011).

Assessment of functional status is of particular importance in urologic oncology trials, as it affects both inclusion criteria and outcomes (Atkinson et al., 2015). The Karnofsky Performance Scale (KPS), first developed in 1949, has been widely used in cancer studies (Karnofsky and Burchanel, 1949). Relatively simple, the KPS is scored by the treating health professional and generates a score from 100% to 0% that incorporates ADLs and overall functional status. A score of 100% represents a normal ability to work and care for one's self with no special care, and a score of 0% represents death. In between, the observer gives the patient a score based on a taxonomy that accounts for issues such as need for assistance, physical disability, hospitalization for acute illness, and so on. The KPS has been shown to perform relatively well with acceptable interobserver and intraobserver reliability (Schaafsma and Osoba, 1994; Schag et al., 1984).

Another well-known scale that is commonly used in cancer trials is the Eastern Cooperative Oncology Group (ECOG) performance scale. This scale is scored from 0 to 5, with 0 being perfectly active and 5 being dead (Oken et al., 1982). The ECOG scale has been compared with the KPS, and both perform well (Verger et al., 1992). Table 6.4 compares the elements and scoring of the KPS to the ECOG scale. In the future, wearable technologies may provide real-time data regarding functional status that could be incorporated into outcome assessment (Kelly and Shahrokni, 2016).

TABLE 6.4

Comparison of Karnofsky Performance Score to ECOG Grade

KARNOFSKY STATUS	KARNOFSKY SCORE	ECOG GRADE	ECOG STATUS
Normal, no complaints	100	0	Fully active and able to carry out all predisease performance without restriction
Able to carry on normal activities. Minor signs or symptoms of disease.	90	1	Restricted in physically strenuous activity but ambulatory and able to carry out light work/activity
Normal activity with effort	80	1	Restricted in physically strenuous activity but ambulatory and able to carry out light work/activity
Can care for self but unable to carry on normal activity or to do active work	70	2	Ambulatory and capable of all self care but unable to carry out work activities. Up and about for more than 50% of waking hours.
Requires occasional	60	2	Ambulatory and capable of all

assistance but able to care for most of one's own needs			self care but unable to carry out work activities. Up and about for more than 50% of waking hours.
Requires considerable assistance and frequent medical care	50	3	Capable of only limited self care. Confined to bed or chair more than 50% of waking hours.
Disabled. Requires special care and assistance.	40	3	Capable of only limited self-care. Confined to bed or chair more than 50% of waking hours.
Severely disabled. Hospitalization may be indicated although death not imminent.	30	4	Completely disabled. Cannot carry out self care. Totally confined to bed or chair.
Very sick. Hospitalization required. Active supportive treatment necessary.	20	4	Completely disabled. Cannot carry out self care. Totally confined to bed or chair.
Moribund	10	4	Completely disabled. Cannot carry out self care. Totally confined to bed or chair.
Dead	0	5	Dead

Modified from Oken MM, Creech RH, Tormey DC, et al. Toxicity and response criteria of the Eastern Cooperative Oncology Group, *Am J Clin Oncol* 5(6):649–655, 1982.

Comorbidity

The term *comorbidity* was originally defined by Alvan Feinstein in 1970 (Feinstein, 1970). **It refers to any coexisting ailments that may be present in addition to the disease being studied. Assessment of comorbidity is of profound importance in the study of urologic disease, as comorbid conditions are often confounding variables (as they affect treatment choice), and failure to account for them may lead to selection bias.** One of the best examples of this in urologic literature relates to transurethral resection of the prostate (TURP). Roos et al. (1989) used administrative data in the late 1980s to compare mortality after either open prostatectomy or TURP. With data from roughly 50,000 subjects and 8 years of follow-up data, they noted that men undergoing TURP were 1.45 times more likely to die in the follow-up period than those undergoing open surgery. The Roos study, however, failed to control for comorbidity in the analysis, which might have biased the findings. To address this shortcoming, Concato et al. (1992) meticulously reviewed the charts of 252 men who underwent either TURP or open prostatectomy at a single institution. They used a validated scale to collect detailed comorbidity information from the medical record and included this in their analysis. When they controlled for age and comorbidity at the time of surgery, they noted no differences in 5-year mortality between TURP and open prostatectomy. Other authors have since confirmed the findings of the Concato study (Crowley et al., 1995).

There are many standardized tools available to assess comorbid disease. The best known of these is the Charlson Combined Comorbidity Index (Charlson et al., 1987, 1994). The original Charlson Comorbidity Score was calculated as a total of the patients comorbid conditions, with some conditions being more weighted than others. Conditions that had a weight of one included: myocardial infarction, congestive heart failure, peripheral vascular disease, cerebrovascular disease, dementia, chronic pulmonary disease, connective tissue disease, peptic ulcer disease, mild liver disease, and diabetes. Conditions that had a weight of two included: hemiplegia, moderate or severe renal disease, diabetes with end organ damage, and any malignancy. Moderate to severe liver disease was given a weight of three, and metastatic cancer or full-blown acquired immunodeficiency syndrome was given a weight of six. The scale was developed to predict 1-year mortality in patients to an inpatient medical service (Charlson et al., 1987) but later was shown to predict 3- to 5-year mortality outcomes in patients undergoing general surgery procedures (Charlson et al., 1994). The scale has since been modified into a short-form (Dell'Oglio et al., 2017) and into a scale that can be used in administrative datasets (Deyo et al., 1992). In addition to the Charlson scale, a number of other validated and reliable comorbidity scales have been used in urologic disease (Klabunde et al., 2000; Litwin et al., 2007; Stier et al., 1999).

Frailty

Frailty is a clinically recognizable state of increased vulnerability resulting from an aging-associated decline in reserve and function across multiple physiologic systems (Xue, 2011). Frailty is associated with increased falls, hospitalization, disability, and mortality (Bandeen-Roche et al., 2006; 2015; Fried et al., 2001; Gill et al., 2006).

Fried et al. operationally defined frailty as a condition in which three of the five following criteria are present: low grip strength, low energy, slowed walking speed, low physical activity, and/or unintentional weight loss (Fried et al., 2001, 2004). Using this definition, they showed that frailty was independently predictive of incident falls, declining functional status, hospitalization, and death in a cohort of patients in the Cardiovascular Health study followed for 3 years (Fried et al., 2001). The Fried definition has since been shown to predicted postoperative complications, length of stay, and discharge to a skilled nursing facility in a cohort of 594 patients presenting for elective surgery (Makary et al., 2010). Frailty has been shown to correlate with surgical outcomes after various urologic procedures including cystectomy (Pearl et al., 2017; Sathianathen et al., 2018), prostatectomy (Levy et al., 2017), and surgery for pelvic organ prolapse (Suskind et al., 2017). As such, it should be controlled for in nonrandomized studies of urologic diseases.

Pain

Postoperative pain is a common endpoint in surgical trials. There are three approaches to pain assessment in research and/or clinical practice. First, one can obtain verbal or written descriptions of the pain. Another approach is to rate the pain via its effect on the observable behavior of the person experiencing it. This can be done by the patient or by an observer. The third approach, which is done almost exclusively in the laboratory setting, is to have the patient compare the pain from his or her condition to an experimentally induced pain stimulus of a known intensity. Most pain assessment in urology is performed using the first approach, that is, having the patient provide a verbal or written description or rating of his or her pain. In the research setting, it is desirable to use one of the many established and validated instruments to capture the patients pain experience, as the findings can be used in statistical analysis.

One way to assess pain is to measure the number of pain pills a patient takes and convert this into “oral morphine equivalents” (McDowell and Newell, 1996). Although this may seem quite objective and unlikely to be subject to bias, further review reveals that this is not the case. Some patients may have a higher “pain tolerance” and will be reluctant to take pain medications, despite considerable discomfort. To this end, it is probably best to directly query patients regarding the severity of the pain they are experiencing. On approach is to ask patients to rate their pain using a series of subjective expressions varying from “no pain at all” to “worst pain imaginable” (McDowell and Newell, 1996). Although this is often enough for clinical care, it is difficult to incorporate this into research. One of the simplest yet most effective ways of capturing pain levels in both the research and the clinical setting is to use of a visual analog scale (VAS). A VAS is usually portrayed as a straight line (usually 10 cm long) which represents a continuum on which the pain is rated. The two ends are usually anchored with one end being “pain as bad as it could be” and the other being “no pain.” The subject marks a spot on the line, and the distance from one end to this mark is measured in millimeters and recorded from 0 to 100, which is then considered the pain score (Scott and Huskisson, 1976). Other authors have used variations of this grading system, providing a numerical scale from 0 to 10 (Downie et al., 1978) or inserting descriptive terms such as *severe, moderate*, or *mild* along the line (Scott and Huskisson, 1976). In addition to the VAS, there are a number of multiple-item pain questionnaires that can be used in the study of urologic conditions. These include the 20-item McGill Pain Questionnaire (Melzack, 1975) and the 20-item Brief Pain Inventory (Cleeland and Ryan, 1994; Cleeland et al., 1994). More recently, the National Institutes of Health PROMIS program also developed a validated and reliable item bank of pain-related questions (Revicki et al., 2009). These questionnaires capture the pain experience in much greater detail and lend themselves to use in clinical research.

Patient-Reported Outcomes

The goal of many urologic interventions is to relieve symptoms caused by benign or malignant conditions. **Although symptoms can affect quality of life, symptom assessment is inherently different than health-related quality-of-life assessment** (Gill and Feinstein, 1994)**. Health-related quality of life (HRQoL) is a patient-reported outcome that encompasses the global impact of disease and disease treatment on a patient's well-being and his or her ability to function in daily life** (Wan et al., n.d.). A key element of HRQoL that distinguishes it from a symptom scale is the inclusion of function and bother elements. In other words, the survey captures not only the degree of symptoms a patient has, but also how much of a problem this is for the individual (Gill and Feinstein, 1994). HRQoL is discussed in much greater detail later in this chapter. When specifically assessing patient-reported symptoms, it is important to remember that symptoms are the physical manifestations of a condition or disease. To this end, they can be assessed a variety of ways, depending on the condition of interest and the nature of the symptom.

One common error that clinicians make is to believe that they can assess patient-centered outcomes from their clinical interaction with the patient. This often leads to unreliable results and introduces considerable bias into any study, as patients often minimize their symptoms to please their treating physicians and/or physicians fail to capture the true severity of the patient's symptoms. To document this, Litwin et al. compared patient report of symptoms using a well-known validated and reliable survey tool to their physician's estimates of the patient's symptoms (Litwin et al., 1998a, 1998b). The treating physicians consistently underestimated the degree of urinary, sexual, and bowel dysfunction the patient experienced, in addition to underestimating the degree of fatigue and bony pain. This study and others (Bennett et al., 1997) underscore the need to collect these data directly from the patient.

Methods of Assessing Patient-Reported Outcomes

There are generally two methods for assessing patient-reported outcomes: patient-completed questionnaires and researcher-administered interviews.

Because interviews are time and labor intensive, questionnaires (also referred to as *surveys* or *instruments*) are typically preferred. Instruments are usually inexpensive, practical, and easy to administer. That being said, these instruments require a rigorous process of development and implementation to ensure they accurately capture what the researchers intend to capture.

Instrument development is a multistep process that begins by determining what patient-reported outcomes the developers wish to measure, then generating and assembling questions into a single instrument and finally performing a psychometric analysis (Vickery et al., 2001). Question, or item, development ideally involves input from multiple perspectives, such as physicians, patients, epidemiologists, and psychologists and usually includes a literature review of existing tools to identify if validated surveys already exist in the space. Initial pilot testing of proposed surveys is also performed to identify readability and redundancy of the new tool (Sung et al., 2016).

Item responses are recorded on either a Likert scale, in which several answer options are presented in a categorical fashion, or a visual analog scale, where patients mark their answer along a continuum between two ends of a spectrum (Voutilainen et al., 2016). Most patient-reported outcomes tools use Likert scales because of easier data capture and simplicity of answering. There are several factors to consider in instrument development. Each item must be written below an eighth-grade reading level, free of abbreviations and complex terms, and contain only one question to ensure patient comprehension (Paasche-Orlow et al., 2003). There is generally a trade-off between breadth (number of domains) and depth (number of items) of assessment. To minimize patient burden, a balance must be struck between the two, with a possible bias toward breadth given the uncertainty of the impact of a disease or treatment (Ware, 1984).

Traditionally, once a preliminary tool has been created, it undergoes psychometric analysis to assess its measurement properties (Nunnally, 1978; Rothrock et al., 2011). **Instruments are tested for the psychometric properties of reliability and validity. Reliability refers to the instrument's precision, or freedom from measurement error.** A number of different measures of reliability are usually assessed. The two most common are internal consistency and test-retest. Internal consistency reliability is the amount of internal agreement among items (Streiner, 2003). For instance, all items intended to measure functional status should score similarly and correlate highly. The goal is to strike a balance between precise measurement of a particular concept without too many items assessing the same theme. Internal consistency reliability is quantified with Cronbach's coefficient alpha (Cronbach, 1951). A value of greater than 0.7 indicates good reliability; however, if it is too high (>0.9), the instrument may have excessive homogeneity suggesting item redundancy. Test-retest reliability represents how reproducible an instrument's results are over time (Litwin, 1995). It is usually measured by administering the instrument to the same subject within a relatively short time span, often a matter of weeks. The time span should be short enough so it is unlikely for the patient's experience to change but long enough so that the instrument seems “fresh” to the patient. Test-retest reliability is quantified using the correlation coefficient statistic, with greater than 0.7 considered highly reliable (Litwin, 1995).

If reliability assesses how reproducible an instrument's results are, validity assesses how well an instrument measures the patient experience it is intended to measure (Nunnally, 1978). Because validity varies based on the context and population for which it is used, it must be assessed separately for different clinical scenarios. For example, an instrument validated to measure incontinence symptoms in neurogenic bladder patients may not accurately measure the same symptoms in prostate cancer patients and, to this end, it should be validated in this second population before it is used in prostate cancer studies (Reeve et al., 2007). There are three types of validity: face, construct, and criterion. Face validity, also known as *content validity,* is a subjective assessment of how well the instrument measures the outcome it is designed to assess. It represents the general impression of experts in the field as to whether the instrument includes necessary items and does not include irrelevant ones (Gill and Feinstein, 1994). Criterion validity is best defined as the correlation between the instrument’s results and those of an accepted “gold standard” or “objective” measure (American Psychological Association, 1974). For example, one might correlate the findings of a new instrument to assess bladder outlet obstruction symptoms with uroflowmetry results. An instrument is highly valid if it scores similarly and correlates highly (r >0.7) with the gold standard. Finally, construct validity is a retrospective assessment of how well an instrument measures what it was designed to measure. Construct validity represents a “gestalt” around instrument performance and can be difficult to assess and often takes years of instrument use before establishing. Two methods for evaluating construct validity are convergent and divergent validity (Parkinson and Konety, 2004). Convergent validity is established when different instruments designed to theoretically measure the same concept are compared and obtain similar results. Conversely, divergent validity is established when instruments measuring unrelated concepts have opposite results. Correlation coefficients are usually used to assess construct validity (Litwin, 1995).

A key characteristic of patient-reported outcomes tools that is often poorly assessed is instrument responsiveness, or how well it detects a clinically meaningful change over time. For some commonly used instruments in urology, this has been studied and is well documented. For example, the smallest clinically meaningful difference in American Urological Association-Symptom Index scores has been studied has was noted to be 3.1 points (Barry et al., 1995b). For many other commonly used instruments in urology, clinically meaningful differences have not been studied or clearly determined. In these cases, although there is no number universally regarded as clinically meaningful, setting the clinically meaningful difference to at least one-half the instrument's standard deviation is a good rule of thumb (Norman et al., 2003).

Specific Symptom Scales

Lower Urinary Tract Symptoms

Valid assessment of lower urinary tract symptoms (LUTS) is critical as these symptoms are seen in many urologic conditions. As such, there are a number of symptom indices that have been shown to be valid and reliable for the assessment of LUTS. Although many of these scales were originally developed for use in men with benign prostatic hyperplasia, they have since been used in women with LUTS and have been found to be valid in both genders (Zhang et al., 2017). **The best LUTS symptom scale is the I-PSS (International Prostate Symptom Score), also know is the American Urological Association (AUA) Symptom Score** (Barry, et al., 1992). The I-PSS is a seven-item survey designed to assess symptom severity in patients with benign prostatic hyperplasia (BPH) (Barry et al., 1992a, 1992b). Although the tool is quite effective in capturing the objective degree of LUTS severity, (Barry, et al., 1995b), it does not really capture the impact of symptoms on quality of life. To this end, the I-PSS is often given in conjunction with the BPH impact index (BII), which consists of four items designed to measure the specific impact of LUTS on general HRQoL (Barry et al., 1995a). The BII has been shown to correlate with a number of general HRQoL instruments, including the general health index and the mental health index of the SF-36 HRQoL instrument (Barry, et al., 1992b).

Although these instruments are the most commonly used LUTS scales and have been used in a number of large, well-known randomized clinical trials to assess the response of LUTS to therapy (Lepor et al., 1996; McConnell et al., 1998, 2003), there are a number of other questionnaires that have been shown to function well in patients with lower urinary tract symptoms. The International Continence Society (ICS) short form ICSmale questionnaire consists of 11 questions (Donovan et al., 1996, 2000). It has the advantage of generating separate voiding and continence summary scores, which may be useful to some researchers. Finally, the DAN-PSS-I (Danish Prostatic Symptom Score) is a 12-item questionnaire that assesses function and bother related to a series of urinary symptoms (Meyhoff et al., 1993). This instrument is unique in that the final score is weighted by the degree of dysfunction and patient-perceived bother. The choice of which symptom scale to use is best driven by the research questions under study. A brief description of the available instruments to assess LUTS specifically in men is presented in Table 6.5.

TABLE 6.5

Selected Patient-Reported Outcomes Tools for Use Primarily in Men With Lower Urinary Tract Symptoms

INSTRUMENT	LEAD AUTHOR, YEAR	NUMBER OF ITEMS	DESCRIPTION
International Prostate Symptom Score (I-PSS)	Barry et al., 1992a	7	Also known as the AUA symptom score, functional scale scored from 0–35; gold standard for patient-reported outcomes in BPH
BPH Impact Index (BII)	Barry et al., 1995a	4	Assesses impact of BPH on quality of life
ICSmale questionnaire	Donovan et al., 2000	11	Assesses voiding and continence separately
Danish Prostatic Symptom Score (DAN-PSS-I)	Meyhoff et al., 1993	12	Generates a weighted score that accounts for urinary function and personal preferences
ICIQ-Nocturia Quality of Life Question (ICIQ-Nqol)	Mock et al., 2008	12	Tested in both men and women. Focuses on two thematic areas only. There is also a single item (in addition to the 12 in the primary instrument) that addresses bother caused by nocturia.

Urinary Incontinence

Although incontinence is certainly a lower urinary tract symptom in and of itself, there are a number of symptom scales designed specifically to assess this common constellation of symptoms in urologic patients. Incontinence can sometimes be documented in the office setting and/or during urodynamics, but this is not always feasible. Furthermore, assessment of incontinence in these settings often does not capture the severity of symptoms to the degree required in the research setting. The clinic and/or urodynamics suite is a somewhat artificial environment, and the fact that incontinence cannot be documented in the clinic does not mean that the patient does not experience leakage at home, work, and so on.

Some researchers have suggested the use of a pad test as a more objective way to assess the severity of urinary incontinence during the usual ADLs (Nygaard, 2004). The patient weighs pads over the course of a day and reports this back to the clinician giving a more quantifiable and objective measure of the degree of incontinence. Although this may be the case, there may also be differences in the way patients use pads, leakage around the pads, and other factors that influence the results of a pad test. In addition, the optimal duration of the pad test to reliably capture the degree of incontinence is unclear. Studies have shown that there is no correlation between 1-hour and 48-hour pad tests. It is clear that longer pad tests produce more reproducible results. In one study, the correlation coefficient between leakage observed in two 24-hour pad tests was 0.66 (Victor et al., 1987). This increased to 0.90 when two 48-hour tests were compared, supporting the need for a longer duration for pad testing (Jorgensen et al., 1987). **It is important to note that the pad test neither distinguishes between urge and stress incontinence nor captures the degree of bother experienced by patients. Two patients may have equal degrees of leakage, yet one is much more limited and bothered by the incontinence than the other. To this end, patient-reported measures are really required to comprehensively understand outcomes related to urinary incontinence.**

There are numerous instruments available for use in incontinence, many of which are geared toward use in women, but some can be used in both genders. The BFLUTS (Bristol Female Lower Urinary Tract Symptoms) instrument is a modified version of the ICSmale survey questionnaire (Jackson et al., 1996, Brookes et al., 2004), The BFLUTS contains 33 items that address urinary incontinence, voiding symptoms in the voiding and storage phases, sexual function, and other aspects of quality of life. The BFLUTS tool goes beyond simple symptom assessment as it captures both function and bother in the urinary domain, making it more of a disease-specific HRQoL tool. It, however, has been used sparingly in men (Heidler et al., 2010).

Similar to the BFLUTS instrument, The IIQ (Incontinence Impact Questionnaire) and the UDI (Urogenital Distress Inventory) are two of the common questionnaires for use in incontinence that, when used together, capture disease-specific HRQoL in this condition (as they capture both function and bother). Developed in the mid-1990s, the original versions of these questionnaires were specifically designed for use in women and were relatively long (roughly 53 items combined) (Shumaker et al., 1994). This was remedied with the development of short-form versions of these questionnaires, the IIQ-7 and the UDI-6 (Uebersax et al., 1995). The shortened surveys focus specifically on the severity and impact of urinary urgency, frequency, and incontinence. Although not originally developed for men, the IIQ-7 and UDI-6 have since been used in a population of older men and performed well (Beaulieu et al., 1999; Coyne et al., 2006; Moore and Jensen, 2000; Moore et al., 1999). These tools have also been modified to focus more on urge incontinence. Lubeck et al. developed modified versions of the IIQ and UDI, known as the U-IIQ (Urge-Incontinence Impact Questionnaire) and the U-UDI (Urge-Urinary Distress Inventory) for use in patients with overactive bladder (OAB) and predominantly urge incontinence (Lubeck et al., 1999). The U-IIQ and the U-UDI are longer (42 items) than the IIQ-7 and UDI-6 and comprehensively capture the severity of urge symptoms and their impact on travel, feelings, physical activities, relationships, and sexual function. The instrument has good psychometric properties and appears to capture most of the psychosocial concerns of patients with urge incontinence and overactive bladder.

Other surveys for use in incontinence tend to focus less on symptoms and functional status and more on the impact of urinary symptoms on quality of life and daily activities. For example, Kelleher et al. developed a 21-item survey, known as the King's Health Questionnaire, to assess HRQoL in incontinent women (Kelleher et al., 1997). Although this questionnaire assesses urinary symptoms and severity of incontinence, it also focuses on general health, incontinence impact, role limitations, physical limitations, social limitations, personal limitations, emotional problems, and sleep disturbances. This makes it more of a HRQoL instrument than a simple symptom scale. It has been shown to be valid and reliable, and it correlates well with outcomes from the SF-36 (Kelleher et al., 1997).

Finally, in the area of urinary incontinence, there are tools that focus exclusively on disease impact and quality of life and do not capture symptoms at all. For example, Patrick et al. (1999) developed the I-QOL (Incontinence Quality of Life), a 22-item questionnaire that assesses avoidance and limiting behavior because of incontinence, social embarrassment, and psychosocial impact of incontinence. This instrument has been tested in both sexes and has been cross-culturally adapted for use in numerous countries in various languages. It does not capture symptom severity, and this should be captured using an additional method (e.g., pad tests, voiding diaries, or symptom scales). A general overview of available patient surveys for assessing urinary incontinence outcomes is presented in Table 6.6.

TABLE 6.6

Selected Patient-Reported Outcomes Tools for Use Primarily in Women With Urinary Incontinence

INSTRUMENT	LEAD AUTHOR(S), YEAR(S)	NUMBER OF ITEMS	DESCRIPTION
Bristol Female Lower Urinary Tract Symptoms (BFLUTS) Questionnaire	Jackson et al., 1996	33	Designed specifically for female incontinence; assesses numerous domains included quality of life.
International Consultation on Incontinence Questionnaire-Female Lower Urinary Symptoms (ICIQ-FLUTS)	Brookes et al., 2004	12	Modified from the BFLUTS. The instrument was reduced to 12 items and also contains an additional 7 items, 2 of which deal with sexual function and 5 of which deal with quality of life.
Incontinence Impact Questionnaire (IIQ) and Urogenital Distress Inventory (UDI)	Uebersax et al., 1995; Shumaker et al., 1994	53	Captures function and bother caused by incontinence and other voiding problems, originally intended for use by females only, shortened versions (IIQ-7 and UDI-6) are available.
Urge-Incontinence	Lubeck et al.,	42	Similar to the IIQ and UDI but heavily

Impact Questionnaire (U-IIQ) and Urge-Urinary Distress Inventory (U-UDI)	1999		weighted to assess the impact of urgency and overactive bladder symptoms on urinary function and quality of life.
King's Health Questionnaire	Kelleher et al., 1997	21	Assesses outcomes in 10 domains and has been used in numerous clinical trials.
Incontinence Quality of Life (I-QOL) Instrument	Patrick et al., 1999; Wagner et al., 1996	22	Assesses impact of incontinence on health-related quality of life (HRQoL) in 3 domains, does not assess function.
Overactive Bladder Questionnaire (OAB-Q)	Coyne et al., 2004	32	Includes an 8-item symptoms bother scale and 25 health-related quality-of-life items. Generates 6 subscale scores from 0–100, with 100 being better quality of life/outcomes.
International Consultation on Incontinence Questionnaire (ICIQ)	Avery et al., 2004	4	Consists of 3 scored items that assess how often the subject experiences urinary leakage, how much leakage the patient thinks she experiences, and how much it interferes with everyday life. The fourth item is descriptive and attempts to determine what activities cause leakage.
Symptom Severity Index (SSI) and Symptom Impact Index (SII)	Black et al., 1996	16	Primarily designed for women with stress incontinence. The SSI consists of 13 items designed to assess symptom severity, including how often the subject leaks and what activities they were doing when they did leak. The SII includes 3 items that assess the amount of bother and worry the symptoms cause.
CONTILIFE	Amarenco et al., 2003	28	Validated in women with incontinence in 5 languages. Generates a global HRQoL score and 6 subscale scores from 0–100, with 100 being poorer quality of life.

Sexual Dysfunction

Assessing sexual function outcomes is particularly challenging for a number of reasons. First, there are obvious gender differences that often prevent researchers from using the same end point when assessing response to treatment. Beyond the obvious gender differences, there are numerous additional issues that make outcomes assessment challenging. First, many individuals judge sexual function in the context of relations with a partner. This can make outcomes assessment difficult in patients who do not have a regular partner or voluntarily choose to be sexually inactive. Even when researchers use outcomes that are not dependent on the presence of a partner, subjects may be reluctant to honestly report their function for fear of embarrassment. Importantly, sexual function is multidimensional and encompasses libido, arousal, erection (men), and ejaculation/orgasm. A problem in any of these areas can be perceived as sexual dysfunction and can cause bother for patients.

One might suggest that the best way to assess sexual function outcomes is to use "objective" physiologic tests, such as nocturnal penile tumescence or duplex Doppler ultrasonography (at least in male sexual dysfunction). Unfortunately, these objective studies can also be problematic, as they are usually performed in "clinical" environments, which may not reflect what the patient is experiencing at home on a daily basis. In addition, they may not accurately assess the degree of dysfunction in subjects with psychogenic etiologies (Blander et al., 1999). **To this end, patient-reported outcomes are crucial when assessing sexual function. Although this also has its problems, when done properly, patient survey instruments for use in sexual dysfunction can be expected to obtain valid and reliable outcomes.**

There are more than 20 validated instruments for male sexual dysfunction in addition to a number of additional questionnaires for which there are no published psychometric data available, most of which focus on sexual dysfunction as it relates to both the patient and his partner (Arrington et al., 2004). This may affect the utility of many of these tools when patients do not have a partner. There are few tools that assess sexual function outcomes independent of the role of the partner. One, the EDITS (Erectile Dysfunction Inventory of Treatment Satisfaction) (Althof et al., 1999) does not require a partner and may be useful for assessing response and satisfaction with treatment. EDITS, however, is not intended for use in patients before they are treated or if they elect no therapy, which may limit its utility. In summary, there is no perfect tool of outcomes assessment in male sexual dysfunction, and clinicians and researchers should choose instruments based on the particular clinical setting of

interest and the question they wish to answer.

To comprehensively capture outcomes in male sexual dysfunction, instruments should assess results in various domains, including libido, erection, and orgasm/ejaculation. The International Index of Erectile Dysfunction assesses outcomes in all of these domains and has become the gold standard instrument for assessing outcomes in male erectile dysfunction. This questionnaire includes 15 items, has been shown to be psychometrically sound, and has been used in numerous clinical trials (Rosen et al., 1997). The five items that deal specifically with erectile dysfunction (ED) have been separately validated and are often referred to as SHIM (Sexual Health Inventory for Men) (Cappelleri and Rosen, 2005; Cappelleri et al., 2000). This shortened instrument has also been used in numerous studies, as have some of the individual items from the questionnaire (Barqawi et al., 2005; Mulhall et al., 2004).

Although the SHIM is a concise measure of erectile function that can be successfully used to assess potency in clinical studies, it fails to capture the bother associated with erectile dysfunction, and, as such, it does not truly assess HRQoL changes related to erectile dysfunction. There are, however, a number of instruments that more comprehensively capture HRQoL outcomes in this common condition (Latini et al., 2002; Wagner et al., 1996). An overview of commonly used instruments for assessment of outcomes in male sexual dysfunction is presented in Table 6.7.

TABLE 6.7

Selected Patient-Reported Outcomes Tools for Use in Men With Sexual Dysfunction

INSTRUMENT	LEAD AUTHOR, YEAR	NUMBER OF ITEMS	DESCRIPTION
International Index of Erectile Function (IIEF)	Rosen et al., 1997	15	Gold standard for patient reported outcomes in male sexual dysfunction; generates scores in erection, libido, and orgasm domains.
Sexual Health Inventory for Men (SHIM)	Cappelleri et al., 2005	5	Consists of the 5 IIEF items that address erection.
QOL-MED	Wagner et	18	Assesses HRQoL impact of erectile

	al., 1996		dysfunction (ED) but assumes a partner is present and that the subject is heterosexual.
Psychological Impact of Erectile Dysfunction (PIED) scale	Latini et al., 2002	16	Examines impact of ED on sexual life and overall emotional state; function not assessed.
Index of Premature Ejaculation (IPE)	Althof et al., 2006	10	Focused on ejaculatory function. Generates scores in three domains: control, sexual satisfaction, and distress.
Sexual Quality of Life for Men (SQOL-M)	Abraham et al., 2008	11	Addresses ejaculatory and ED but not libido issues. Correlates well with the overall satisfaction domain of the IIEF.

In contrast with male sexual dysfunction, there are considerably fewer tools for assessing outcomes in female sexual dysfunction (FSD). The BISF-W (Brief Index of Sexual Function for Women) is a 22-item self-report questionnaire (Taylor et al., 1994). The three domains assessed are sexual interest/desire, sexual activity, and sexual satisfaction. When originally developed, there was no single summary score. However, Mazer et al. modified the BISF-W to provide an overall composite score to facilitate use of the instrument in clinical trials (Mazer et al., 2000). The Female Sexual Function Inventory is a 19-item questionnaire that generates scores in the six domains of lubrication, arousal, desire, pain, orgasm, and satisfaction (Meston, 2003; Rosen et al., 2000). It also creates a summary score that can be used in clinical trials. This instrument has been used in a number of studies to date (Padma-Nathan et al., 2003; Salonia et al., 2004).

The DISF (Derogatis Interview for Sexual Functioning) is a unique tool that combines an interview and a self-report questionnaire to evaluate female sexual function (Derogatis, 1997). Each part takes about 15 to 20 minutes to administer. A total of 25 questions in the two parts assess the five domains of sexual cognition and fantasy, sexual arousal, sexual behavior and experiences, orgasm, and sexual drive and relationship. Because of the interview component, this tool has not been widely used and probably is not of value in the clinical urology setting. However, it also provides a more comprehensive portrait of the psychosocial aspects of FSD and may be useful for assessing outcomes in the research setting. In summary, the DISF is probably not needed for most simple studies of FSD. A summary of the available patient-reported measures for use in female sexual function is presented in Table 6.8.

TABLE 6.8

Selected Patient-Reported Outcomes Tools for Use in Females With Sexual Dysfunction (FSD)

INSTRUMENT	LEAD AUTHOR, YEAR	NUMBER OF ITEMS	DESCRIPTION
Brief Index of Sexual Function for Women (BISF-W)	Taylor et al., 1994	22	Assesses female sexual function in 3 domains of interest, activity, and satisfaction
Female Sexual Function Inventory (FSFI)	Rosen et al., 2000	19	Measures outcomes in 6 domains and generates a summary score, becoming the most widely accepted tool in FSD
Derogatis Interview for Sexual Functioning (DISF)	Derogatis, 1997	25	Incorporates an interview and a questionnaire; assesses outcomes in 5 domains

Health-Related Quality of Life

The primary goal of many urologic interventions is to improve patients' quality of life. To this end, researchers need to be able to assess this outcome objectively and accurately. Advances in the assessment of HRQoL over the past three decades have made this possible. HRQoL refers specifically to the elements of a patient's life and existence that are specifically affected by their health status**. It is a broad and multidimensional construct that is difficult to define. HRQoL has been described as a "patient's appraisal of and satisfaction with their current level of functioning as compared to what they perceive to be possible or ideal," and the extent to which "medical interventions impact the functional, psychological, social and economic life" of a patient** (Aaronson et al., 1986; Cella and Tulsky, 1990). In fact, Calman simply defined HRQoL as the gap between a patient's expectations and experiences (Calman, 1984). Components of HRQoL include health perceptions, function, patient preferences, and overall patient satisfaction with care received. Many elements of human experience affect well-being and quality of life, including access to adequate food and shelter, personal responses to illness, and activities associated with professional responsibilities (Patrick and Erickson, 1993).

As mentioned earlier, any assessment of HRQoL should include both a relatively objective assessment of a patient's function coupled with the amount of bother a patient experiences caused by any decrements in their functional status (Gill and Feinstein, 1994). HRQoL instruments can be general or disease-specific in nature (Patrick and Deyo, 1989). General HRQoL instruments assess domains of quality of life that are common in all patients, regardless of the disease process (e.g., functional well-being, emotional well-being, overall health status). Disease-specific HRQoL instruments focus on domains of quality of life that are highly relevant to individuals who suffer from the particular disease process being studied. For example, patients with invasive bladder cancer may be concerned with body image, and sexual and urinary function, and a bladder cancer–specific HRQoL instrument would assess these areas. A listing of some of the available general and disease-specific HRQoL instruments that have been used in studies of urologic conditions is included in Table 6.9.

TABLE 6.9

Selected Health-Related Quality of Life Instruments That Have Been Used in Urologic Diseases

INSTRUMENT	LEAD AUTHOR, YEAR	NUMBER OF ITEMS
GENERAL (GENERIC) HRQoL MEASURES		
Medical Outcomes Study (MOS) SF-36	Ware et al., 1992	36

Functional Assessment of Cancer Therapy—Kidney	Cella et al.,	15

Symptoms Index (FKSI-15)	2006	

Other Outcomes of Interest in Urology

Patient Satisfaction

Over the past decades, there has been increased focus on patient satisfaction with their health care. General patient satisfaction with health care has been used as an outcome in various studies of urologic disease (Kaye et al., 2017; Schoenfelder et al., 2014; Shirk et al., 2016). Perhaps more importantly, however, patient satisfaction scores on the Hospital Consumer Assessment of Healthcare Providers and Systems (HCAHPS) has been tied to hospital reimbursement by Medicare, with hospitals realizing or losing up to 1.5% of their Medicare reimbursements based on these scores. The HCAHPS survey contains 27 items that query recently discharged patients about their hospital stay. The survey contains 18 core questions about critical aspects of patients' hospital experiences (communication with nurses and doctors, responsiveness of hospital staff, cleanliness and quietness of the hospital environment, pain management, communication about medicines, discharge information, overall rating of hospital, and if they would recommend the hospital). The survey also includes four items to direct patients to relevant questions, three items to adjust for the mix of patients across hospitals, and two items that support Congressionally-mandated reports (Centers for Medicare and Medicaid Services, n.d.). There are a number of general patient-satisfaction surveys available for research use, although few if any are focused specifically on urologic disease (Ware and Hays, 1988; Wiggers et al., 1990; Woodward et al., 2000).

Health Care Costs

There is increased focus on the economic costs of health care, as demand for health care outstrips available resources. Accurate cost data have proven difficult to collect because of differences in prices across countries and within regions of the same country, the proprietary nature of economic data, and the fact that different elements of health care costs are borne by different entities (i.e., the patient, the insurer, the employer, the government). Acknowledging this, it is possible to divide the cost of a health care intervention into three components: direct costs, indirect costs, and intangible costs.

Direct costs consist of the actual costs of delivering the intervention. These include inpatient and outpatient services (which includes professional fees, staffing costs, equipment costs, and so on), pharmaceuticals, and other expenses directly related to the delivery of health care. These costs are often difficult to ascertain as mentioned earlier. Traditionally, these costs have been gleaned from administrative databases and/or hospital chargemasters, which may not be accurate (Brill, 2013). One approach to assessing direct costs is to use time-driven activity-based costing (TDABC). This was originally proposed for use in health care by Kaplan and Porter. TDABC consists of identifying the potential clinical path a patient can take during his or her care and then meticulously identifying both the costs of all health care resources consumed and the amount of time spent at each step in pathway (Kaplan and Porter, 2011; Porter, 2010). Although this technique may seem difficult (and perhaps it is), it has already been successfully employed in urology to identify the cost of delivering prostate cancer care (Laviana et al., 2016).

Indirect costs include lost wages to the patient and his or her caregivers and other potential opportunity costs. This is obviously dependent on the age of the patient and his or her social support status, in addition to the severity and length of the condition the patient is suffering from (Finkelstein and Corso, 2003; Gold et al., 1996). Finally, intangible costs consist of the monetary value of pain and suffering, anxiety, and costs to society. These are very difficult to measure and are not usually included as endpoints in clinical research studies.

Key Points

- The effectiveness of health services delivery and treatment can be measured across three distinct dimensions: structure, process, and outcomes. Structure and process measures are easier to assess, but outcomes tend to be most meaningful to clinicians and patients.
- Mortality is the “hardest” endpoint one can assess in urology. That being said, it can be subject to bias. Specifically, studies using overall mortality can still be subject to lead- and length-time bias, and studies using disease-specific mortality may be subject to attribution bias.
- Although there are many proxy endpoints in urology, few meet all four requirements for being a valid surrogate endpoint. Despite this, urologists routinely use proxy endpoints in research and clinical practice.

- There are a number of published and widely accepted criteria for defining disease progression and surgical complications in urology. Although urologists should use these reporting systems whenever possible, they should also remember that use of these systems does not completely eliminate the potential for bias in research because of study design and other factors.
- Frailty, functional status, and comorbidity are important potential confounders that should be considered in urologic research. There are numerous standardized tools available to capture these variables.
- There are numerous patient-reported outcomes tools available to assess symptoms and quality of life in patients with urologic diseases. Physicians and researchers should always use validated and reliable patient-centered tools when possible.

Ethics and Informed Consent

Vijaya M. Vemulakonda MD, JD

As clinical urologic practice continues to become more complex, the ethical and legal implications of practice become more profound. The purpose of this chapter is to provide a brief history of the origins of medical ethics and legal principles of informed consent, to define key ethical principles and their application to clinical decision making, and to consider the ethical and legal requirements for informed consent in both the clinical and surgical settings.

Medical Ethics

History of Medical Ethics

The origins of medical ethics are thought to be rooted in the writings of Hippocrates, considered to be the “father of medicine.” Foremost among his contributions to medicine is the Hippocratic oath (Box 7.1), considered the cornerstone of ancient Greek medical ethics, which postulated that the primary goal of medicine is to protect the patient's interests. **The oath establishes the moral framework governing the physician-patient relationship and introduces the ethical principles of beneficence, nonmaleficence, confidentiality, and accountability to the medical profession** (Antoniou et al., 2010).

Box 7.1

Translation of the Original Hippocratic Oath

I swear by Apollo the physician, and Aesculapius, and Health, and All-heal, and all the gods and goddesses, that, according to my ability and judgment, I will keep this Oath and this stipulation: to reckon him who taught me this Art equally dear to me as my parents, to share my substance with him, and relieve his necessities if required; to look upon his offspring in the same footing as my own brothers, and to teach them this Art, if they shall wish to learn it, without fee or stipulation; and that by precept, lecture, and every other mode of instruction, I will impart a knowledge of the Art to my own sons, and those of my teachers, and to disciples bound by a stipulation and oath according to the law of medicine, but to none others.

I will follow that system of regimen which, according to my ability and judgment, I consider for the benefit of my patients, and abstain from whatever is deleterious and mischievous. I will give no deadly medicine to anyone if asked, nor suggest any such counsel; and in like manner I will not give to a woman a pessary to produce abortion. With purity and with holiness will I pass my life and practice my Art.

I will not cut persons labouring under the stone, but will leave this to be done by men who are practitioners of this work. Into whatever houses I enter, I will

> go into them for the benefit of the sick, and will abstain from any voluntary act of mischief and corruption; and, further, from the seduction of females or males, of freemen and slaves.
>
> Whatever, in connection with my professional practice, or not in connection with it, I see or hear, in the life of men, which ought not to be spoken of abroad, I will not divulge, as reckoning that all such should be kept secret. While I continue to keep this Oath unviolated, may it be granted to me to enjoy life and the practice of the Art, respected by all men, in all times! But should I trespass and violate this Oath, may the reverse be my lot!
>
> From *The Genuine Works of Hippocrates,* translated from the Greek by Francis Adams, Surgeon, volume 2, London, 1849.

However, in the 20th century, the traditional values embodied by the oath were challenged by prominent ethicists such as Robert Veatch. In this view, the oath relies on the physician to make judgments about diagnosis and treatment because of the patient's inability to understand the information needed for decision making. As a result, the oath undermines the growing respect for patient autonomy that emerged during the late 20th century (Veatch, 1991; Veatch, 2009). Additionally, the oath has been criticized for not addressing issues surrounding justice in the allocation of medical resources, instead focusing on the individual outside of the social context of his care (Veatch, 1991).

As criticism of the Hippocratic oath grew, the interdisciplinary field of bioethics emerged. During the 1960s, physicians first began to discuss the impact of technology, such as antibiotics and genetic testing, on medical care (Jonsen, 2001). In 1970 Van Rensselaer Potter first coined the term *bioethics* to describe “the study of the moral relationship between humans and their social and physical world (Jonsen, 2001; Potter, 1970).” Concerns over the eugenic experiments of the Nazis during World War II strengthened the focus on patient autonomy and patient rights to protect their medical and genetic information (Jonsen, 2001). This focus on respect for patient autonomy and informed consent was reinforced in the research realm as information about the Tuskegee syphilis studies became public in the early 1970s (Jonsen, 2001). In 1979 the “Four Principles” framework for addressing ethical issues in medicine was first described by Beauchamp and Childress. This approach remains the cornerstone of modern medical ethics (Beauchamp and Childress, 1979).

The Four-Principles Framework

The four principles delineated by Beauchamp and Childress were developed to help provide a common set of moral commitments and language with which to address ethical issues (Gillon, 1994). **The principles include autonomy, beneficence, nonmaleficence, and justice.** These principles are considered equal in weight and should be considered *prima facie* binding unless in conflict, leading to ethical dilemmas in circumstances in which the physician and patient must prioritize among conflicting principles (Gillon, 1994).

***Autonomy,* described as respect for the "deliberated self-rule" of individuals, includes an obligation to respect that patients are able to make their own choices even if the outcomes of those choices do not coincide with the physician's calculation of maximal benefit and minimal harm** (Gillon, 1994). This principle is grounded in the Kantian "categorical imperative" that people be considered ends in themselves rather than a means to an end. Although some have postulated that autonomy should be prioritized when in conflict with other principles, it is also considered bound by justice or the consideration of autonomy of others in addition to the individual patient (Gillon, 1994). Respect for autonomy provides the foundation for several physician obligations, including informed consent, confidentiality, and avoidance of deceit. Importantly, communication is essential to providing the physician with the information about patient preferences and attitudes needed to guide discussions of options and to frame medical decision making in a way that is respectful of the patient (Gillon, 1994).

Beneficence and nonmaleficence are grounded in the Hippocratic oath's dictum to protect the patient's best interests (Antoniou et al., 2010). ***Beneficence* refers to the physician's obligation to optimize benefit to the patient and should be considered through the prism of the patient's values and preferences *(autonomy)*. *Nonmaleficence* is grounded in the Hippocratic dictum *primum non nocere* (first do no harm) and refers to the obligation to avoid or minimize harm to the patient**. These principles mean that (1) we must be able to provide the benefits we promise, through adequate training, education, and professional standards and (2) we must be clear about the probability and magnitude of risk and benefit associated with treatment to ensure that we are able to optimize the patient's understanding (Gillon, 1994). As a result, the complementary principles of beneficence and nonmaleficence can be seen as an obligation not only to provide training to the individual clinician but also to conduct research to ensure that the information we offer is as accurate as possible. Finally, the weighing of risks and benefits should be considered both at the individual and at the population level *(justice)* to ensure that risks and benefits are equally shared among patients.

***Justice* refers to the obligation to seek and achieve fairness in the distribution of resources, benefits, and risks across patients.** Although equality and justice share many traits, they are not equivalent; “people may be treated unjustly even if they are treated equally” (Gillon, 1994). At the individual patient level, justice means that the physician should try to minimize the effect of self-interest or personal preferences on patient decisions and should respect the patient's right to self-determination. Additionally, the physician should try to minimize waste of resources when possible. At the societal level, determination of justice may be more difficult. Competing values in justice may lead to different outcomes: does just distribution require equal access to care, provision to those who need it most, advocacy by physicians to maximize the benefit for their patients, limitation of societal costs (via taxes or insurance deductibles), or respect for patient choice? Although all of these values have merit, how do we as physicians and as a society determine which should have priority (Gillon, 1994)?

Medical Ethics in Clinical Practice

Despite the focus on these four principles in medical society codes of ethics and in training, the translation of these principles to specific medical care may not always be clear (Page, 2012). To address this issue, Jonsen et al. recommend use of the “Four-Box” technique to provide a more systematic method to consider and apply ethical principles to medical cases (Table 7.1) (Jonsen et al., 1998). The four topics to be considered include the following:

TABLE 7.1

The Four-Box Method to Application of Ethics in Clinical Practice

Medical Indications	Patient Preferences
1. What is the patient's medical problem? History? Diagnosis? Prognosis? 2. Is the problem acute? Chronic? Critical? Emergent? Reversible? 3. What are the goals of treatment? 4. What are the probabilities of success?	1. What has the patient expressed about treatment preferences? 2. Has the patient been informed of benefits and risks, demonstrated understanding, and given consent? 3. Is the patient mentally capable and

5. What are plans in cases of therapeutic failure? 6. In sum, how can this patient be benefited by medical and nursing care and how can harm be avoided?	legally competent? What evidence is there of incapacity? 4. Has the patient expressed prior preferences (e.g., advance directives)? 5. If incapacitated, who is the appropriate surrogate? Is the surrogate using appropriate standards? 6. Is the patient unwilling or unable to cooperate with medical treatment? If so, why? 7. In sum, is the patient's right to choose being respected to the extent possible in ethics and law?
Quality of Life 1. What are the prospects, with or without treatment, for a return to the patient's normal life? 2. Are there biases that might prejudice the provider's evaluation of the patient's quality of life? 3. What physical, mental, and social deficits is the patient likely to experience if treatment succeeds? 4. Is the patient's present or future condition such that continued life might be judged undesirable by him or her? 5. Is there a plan and rationale to forego treatment? 6. What are plans for comfort/palliative care?	Contextual Features 1. Are there family issues that might influence treatment decisions? 2. Are there provider issues that might influence treatment decisions? 3. Are there financial and economic factors? 4. Are there religious or cultural factors? 5. Is there any justification to breach confidentiality? 6. Are there problems of resource allocation? 7. What are the legal implications of treatment decisions? 8. Is clinical research or teaching involved? 9. Are there any provider or institutional conflicts of interest?

Modified from Jonsen AR, Siegler M, Winslade WJ. *Clinical ethics: a practical approach to ethical decisions in clinical medicine.* 4th ed. McGraw-Hill; 1998.

***Medical Indications* include the general goals of medical treatment (prevention and care of illness) and are grounded in the principles of beneficence and nonmaleficence** (Jonsen et al., 1998). In addition to discussion of clinical issues and potential treatment options, this discussion should extend to the goals of intervention. To act ethically, the physician must use his or her clinical judgment to evaluate the potential risks and benefits of treatment, to make a recommendation based on this assessment, and to identify the patient's preferences regarding treatment choice. The physician should consider and discuss with the patient potential clinical uncertainty both in terms of suspected diagnosis and outcomes. Additionally, when the risks and benefits of treatment appear to be equivocal, the physician should defer to the patient's stated preferences (Schumann and Alfandre, 2008).

***Patient Preferences* refer to the patient's values and assessment of relative benefits of treatment alternatives and are grounded in the ethical principle of autonomy** (Schumann and Alfandre, 2008). To ensure adequate consideration of patient preferences, the provider must ensure the patient has sufficient information and comprehension to weigh treatment options. Additionally, the provider should ensure that the patient has a clear understanding of the uncertainty in outcome and the potential range of treatment choices and outcomes. Finally, it is essential to ensure the patient's choice is voluntary. In the setting of lack of adequate capacity, the physician should ensure that the appropriate person has been identified to act as the patient's surrogate and is acting in accordance with the patient's beliefs and wishes when possible (Schumann and Alfandre, 2008).

***Quality of Life* is the most ephemeral of the factors to be considered in practice and stems from the principles of autonomy, beneficence, and nonmaleficence** (Schumann and Alfandre, 2008). As a result of the variable understanding of this term, it may be difficult for the provider to intuit the impact of treatment on the patient's perceived quality of life. As a result, the substitution of the provider's views for the patient's raises concerns about potential bias that should be considered in the decision-making process, and the provider should try to elicit from the patient his or her values and preferences to guide assessment of quality of life (Jonsen et al., 1998).

***Contextual Features* allow for consideration of a patient-physician partnership within the greater framework of personal, institutional, legal, and social relationships and is grounded in the ethical principle of justice**. This may include family dynamics, patient socioeconomic circumstances, as well as religious beliefs (Schumann and Alfandre, 2008). Additionally, this topic includes the dynamics of the treatment team, the need for coordination of care among multiple providers, as well as potential physician biases or interests that may affect treatment decisions (Jonsen et al., 1998).

Although the Four-Box framework allows for a systematic approach to assessing clinical conundrums by providing an easy-to use-technique for organizing conflicting priorities in patient care and for discussing areas of conflict with the patient and family, it may also lead to oversimplification of ethical issues and may not always clearly guide clinical decision making within the context of identified ethical concerns. **As a result, this framework (or any ethical model) should be used in conjunction with the surgeon's assessment of reasonable alternatives for treatment as a vehicle to guide discussion of the relative benefits of each alternative through the prism of the patient's preferences.**

Informed Consent

History of Informed Consent

Although now considered within the scope of negligence, the legal concept of informed consent originated in early 20th century battery law. From 1905 to 1914, state courts identified a right to bodily integrity that required physicians to obtain informed consent before performing a procedure. They found that patients have the right to decide their course of treatment, and as part of that right, they are entitled to be informed about the risks associated with the procedure and to evaluate those risks before coming to a decision (Faden and Beauchamp, 1986). Patients also may limit the consent provided. For example, consent for an examination under anesthesia does not extend to a consent to surgery (Schloendorff, 1914). Furthermore, consultation for medical advice from a physician does not imply consent (Mohr vs. Williams, 1905). Although the courts did acknowledge the potential for implied consent, this was limited to emergency situations or to cases in which a life-threatening condition was identified and the patient was not capable of consent (Faden and Beauchamp, 1986; Luka vs. Lowrie, 1912).

In 1957 the term *informed consent* was coined and included that physicians provide "any facts which are necessary to form the basis of an intelligent consent by the patient to the proposed treatment" (Salgo vs. Leland, 1957). Under this new standard, physicians faced a heightened responsibility to provide information about the risks, benefits, and alternatives to a procedure to facilitate an informed decision by the patient. The Kansas Supreme Court in 1960 found that physician liability for failure to adequately inform a patient about the risks associated with treatment fell within the scope of negligence. As a result, the legal standard for violating informed consent required both establishing that a physician's actions fell outside of the scope of what a "reasonable and prudent" physician would do and that these actions were the "proximate cause" of the subsequent harm (Katz, 1977). This standard was expanded in 1972 by the DC Court of Appeals, which found that the disclosure should fit within what a "reasonable person" would want to know rather than deferring to what a "reasonable physician" would disclose (Canterbury vs Spence, 1972).

Elements of Informed Consent

Informed consent refers to the process by which a patient and medical provider discuss a proposed medical treatment, its anticipated consequences, potential risks and benefits, and alternatives. This process allows for open discussion between the provider and the patient and may theoretically help reduce medical errors, improve patient outcomes, and increase patient empowerment (Cordasco, 2013).

A comprehensive informed consent consists of four basic elements: (1) description of the clinical problem, the proposed treatment, and alternatives including no treatment; (2) discussion of the risks and benefits of the proposed treatment with comparisons to the risks and benefits of alternatives, and discussion of medical/clinical uncertainties regarding the proposed treatment; (3) assessment of the patient's understanding of the information provided by the medical provider; and (4) solicitation of the patient's preference and consent for treatment (Cordasco, 2013).

The extent of information to be provided is generally based on the physician's assessment of what information may impact diagnosis and treatment planning. Extraneous information that is unlikely to impact the patient's decision may be withheld. Additionally, to the extent possible, information should be provided in a way that is understandable to the average layperson and facilitates his or her meaningful participation in treatment planning. By discussing options before making a recommendation, the surgeon may reduce undue influence on the patient's decision (McCullough et al., 1986).

To ensure adequate information for consent, patients must understand the “material risks” and expected benefits of treatment. However, there is no clear consensus on what constitutes a material risk. Some have proposed a 1% risk cutoff, with lower risk considered based on the severity of harm (Adams and Smith, 2001). Additionally, there are several limitations to patient understanding of risks. First, patients often use shortcuts to simplify the decision-making process, often leading to misunderstanding of the risks posed by a treatment (Lloyd, 2001). Second, patients may underestimate their own risks compared with other people's (Weinstein, 1989). Third, patients are influenced by the way in which risks are presented (e.g., likelihood of survival versus likelihood of death) (Lloyd, 2001). Counterintuitively, information about clinical uncertainty in the probability of risk improves understanding of risk and also elicits more trust in the information provided (Johnson and Slovic, 1995).

Patients often idealize surgeons and accept surgical recommendations without meaningful participation in the decision-making process (McNeally and Martin, 2000). As a result, the surgeon has a heightened responsibility to solicit patient feedback during the consent process. By empowering the patient to both ask questions and to authorize surgical intervention, the surgeon also strengthens their relationship with the patient, opening the door to an ongoing process of communication before, during, and after treatment (Jones et al., 2007). Substantively, the physician should ensure that the patient understands the goals of treatment, the general nature of the procedure to be performed, as well as expected outcomes including what to expect in the immediate postoperative period.

The last element of the informed consent process is explicit consent or refusal of treatment based on the information and recommendations provided by the surgeon. The surgeon should help the patient understand the potential future implications of his or her decisions. The extent to which the surgeon directs the conversation regarding treatment alternatives may depend on how active the patient chooses to be in the decision-making process (Fig. 7.1). Regardless of the patient's role in the process, the surgeon should at least ensure patient understanding of the potential outcomes, risks, and benefits associated with the procedure before obtaining consent. To facilitate the patient's judgments about the relative risks and benefits of treatment, the surgeon may ask the patient about what elements of treatment are most important to him or her, such as impact on job performance, sexual function, continence, or ability to pursue leisure activities.

Exceptions to the Informed Consent Requirement

Emergency situations: One of the well-established exceptions to informed consent is in the emergency setting. **In this setting, where there is a significant threat to patient's well-being or life, consent is presumed** (Hartman and Liang, 1999). In unconscious patients in need of emergent medical care, the responsibility of disclosure is waived because of the potential irreparable harm that may result (Barnett vs. Bachrach, 1943). Similarly, in the pediatric setting, informed consent from the parents may be waived if the patient is at risk for “immediate injury or death (Hartman and Liang, 1999).” However, this waiver does not extend to the conscious patient, who may refuse treatment even if to do so would be life-threatening (In re Quackenbush, 1978) or to children where obtaining parental consent does not constitute an immediate threat of harm (Rogers vs Sells, 1936).

Patients without decision-making capacity: **In patients who are unable to participate in the decision-making process, often family members are empowered by law to make decisions for them** (Areen, 1987). The goal is for the family to assess what the patient would consider most important (“substituted judgment”) rather than for the family to make decisions based on their own values. In cases in which the family is unable to achieve substituted judgment, they should instead act in the best interest of their loved one. When the surgeon does not believe that the surrogate decision maker is adequately pursuing the patient's wishes, he or she should then consult with the institutional ethics board or hospital administration to determine whether petitioning the court for a conservator is warranted (McCullough et al., 1986).

Pediatric patients: **Although by law parents are considered surrogate decision makers for minor children (younger than 18 years of age), children should participate in the decision-making process to the extent that they are able** (Committee on Bioethics, American Academy of Pediatrics, 1995). When parents and their children disagree about the best treatment decision, the surgeon should offer to facilitate discussion to help them reach a common decision. Additionally, providing information about the process, including providing families with the opportunity to visit perioperative spaces before surgery, may help improve understanding and alleviate anxiety about the process (Ziegler and

Prior, 1994).

Quality of Informed Consent

In assessing the quality of consent, two questions must be answered: (1) Did the physician provide the patient with enough information about the diagnosis and treatment and (2) Did the patient consent to treatment based on this information (Jones et al., 2007)? **The standard by which to judge the adequacy of information should be based on what a reasonable person (patient) needs for a meaningful decision** (Canterbury vs. Spence, 1972) **and includes a responsibility for the physician to respect the patient's perspective of his or her interests whether or not the physician agrees** (Jones et al., 2007).

Despite the need for effective consent, most informed consent processes are incomplete, with the most common missed element being assessment of patient understanding of the information provided by the physician (Cordasco, 2013). The information provided in consent forms often is above the 12th-grade level, although the majority of patients have reading levels well below that (Hopper et al., 1998). Whether because of the difficulty of understanding or recalling the information in informed consent documents, patients who report reading consent forms do not demonstrate better understanding of the procedure and its risks than those who do not (Cassileth et al., 1980). This lack of understanding is even more pronounced in patients with limited English proficiency (Cordasco, 2013).

To address these limitations, several techniques have been tried to improve the informed consent process. Simplifying consent forms alone has had mixed results in improving patient understanding (Cordasco, 2013). Supplemental written materials providing information about the procedure in more simplified language than the consent form has had a more significant impact on patient recall of information (Cordasco, 2013). Similarly, decision aids with more detailed information about options and potential outcomes have improved knowledge about procedures, reduced decisional conflict, improved patient participation in the decision, and improved risk assessment (O'Connor et al., 2009). Finally, use of “repeat-back” methods in which the patient is asked to explain what he or she has been told and the provider then clarifies the information provided with subsequent repeat assessments of patient knowledge has been found to be effective in improving comprehension but also adds significant time to the patient-provider encounter, limiting its potential feasibility

(Fink et al., 2010).

Key Points

- Although the scope of medical ethics continues to evolve, the basic ethical principles of autonomy, beneficence, nonmaleficence, and justice remain the foundation of ethical medical practice.
- Informed consent is essential to the practice of surgery with limited exceptions.
- Despite the goal of ensuring adequate understanding of the nature, risks, benefits, and alternatives of surgery to facilitate a meaningful decision, the informed consent process is often incomplete. It is therefore the responsibility of the surgeon to make every effort to facilitate patient understanding and participation in the decision-making process.

Principles of Urologic Surgery

Perioperative Care

Simpa S. Salami MD, MPH

The perioperative care of the urology patient continues to evolve as newer tools and techniques are introduced and as the population ages. Over the past two decades, the economics of health care have added increasing pressure for more outpatient surgery, decreased hospital stays, and decreased complication rates. It has become the standard of care for patients undergoing even the most sophisticated and complex urologic procedures to be admitted on the same day as the surgery and discharged to home the day after surgery. Further, although the practice of urology continues to move toward office-based and nonsurgical treatments, the diversity of genitourinary disease requires that the practicing urologist be familiar with perioperative surgical principles to improve clinical care and outcomes. This chapter provides the reader with basic tools to understand the preoperative assessment and optimization, intraoperative and postoperative management approaches necessary to promote a culture of patient safety and effective and efficient clinical care, and to ensure optimal surgical outcomes.

Preoperative Evaluation

The acuity of surgical patients is increasing as the population ages and as patients present with more significant comorbidities. **The urologic surgeon is responsible for ensuring that the patient has been thoroughly evaluated by the other physicians on the health care team and arrives in and leaves the operating room in the most optimized medical condition.** The preoperative use of appropriate medical specialist consultations not only will result in improved patient safety and outcomes but will also obviate the need for unnecessary cancelled surgeries resulting from the inadequacy of medical optimization.

Presurgical Testing

The goal of presurgical testing is to identify an undiagnosed comorbidity, an undertreated pre-existing medical problem, or a significant exacerbation of existing comorbid illness that may affect the operative course and/or outcome (Townsend et al., 2015). Ideally, the preoperative evaluation should be individualized on the basis of age, history, physical examination findings, and the surgical procedure to be performed. Although most hospitals or ambulatory surgery centers have requirements for baseline evaluation, routine testing in addition to history and physical examination has never been shown to be cost-effective. In fact, the results of routine testing are less predictive of perioperative morbidity than the American Society of Anesthesiologists (ASA) status or the American Heart Association (AHA) and American College of Cardiology (ACC) guidelines for surgical risk. A recent systematic review found no evidence to support routine preoperative testing in patients undergoing noncardiac elective surgery (Johansson et al., 2013). Most commonly, presurgical testing includes complete blood count (CBC); basic metabolic panel (BMP); prothrombin time (PT), partial thromboplastin time (PTT), and international normalized ratio (INR) (controversial); electrocardiogram (ECG); ABO/Rh blood typing and antibodies screen; and chest radiograph. The routine ordering of a PT/PTT in a patient not currently on anticoagulation or in a patient without a prior history of a bleeding disorder or increased bleeding with other surgical procedures is controversial, and these tests can be omitted in the majority of patients. **Any woman of childbearing age, unless the ovaries or uterus have been previously surgically removed, must undergo a urine pregnancy test on the morning of surgery** (Halaszynski et al., 2004). The value of a preoperative ECG in identification of underlying acute cardiac disease and prediction of perioperative cardiac morbidity is also controversial. Some studies have shown that ECG abnormalities have no significant added predictive value (van Klei et al., 2007; Liu et al., 2002), whereas others found that an abnormal ECG preoperatively is a predictor of an adverse cardiac event in patients undergoing noncardiac surgery (Noordzij et al., 2006; Biteker et al., 2012; Shoyeb et al., 2006). Nonetheless, current recommendations, in general, suggest that a preoperative ECG be obtained from patients older than 40 years of age or those with a history of cardiac disease. Similarly, the routine preoperative use of a chest radiograph, in the absence of preexisting cardiopulmonary disease, is not indicated. Overall, even an ASA Task Force on Pre-anesthesia Evaluation could not make firm recommendations other than “preoperative tests may be ordered, required, or *performed on a selective basis* for purposes of guiding or optimizing perioperative management” (Committee on Standards and Practice Parameters et al., 2012).

American Society of Anesthesiologists Classification and Risk

Approximately 27 million patients undergo surgery each year in the United States, and 8 million (30%) have significant coronary artery disease or other cardiac comorbidities. Appropriately, the cardiovascular system is targeted during the preoperative assessment of patients. The ASA classification was first developed in 1961 and has been revised to categorize risk into six stratifications (Box 8.1).

Box 8.1

American Society of Anesthesiologists (ASA) Classification

1	ASA Class I	Normal healthy patient
2	ASA Class II	Patient with mild systemic disease
3	ASA Class III	Patient with severe systemic disease that limits activity but is not incapacitating
4	ASA Class IV	Patient with incapacitating disease that is a constant threat to life
5	ASA Class V	Moribund patient not expected to survive 24 hours with or without an operation
6	ASA Class VI	A declared brain-dead patient whose organs are being removed for donor purposes
7	ASA Class E	In the event of emergency surgery, an E is added after the Roman numeral (in I through V classes)

The goal of the classification system is to assess the overall physical status of the patient before surgery (not to assess surgical risk), and although quite subjective, it remains a significant independent predictor of mortality (Davenport et al., 2006). Other tools to assess the preoperative risks were developed by multivariate statistical analysis of patient-related factors correlated with surgical outcomes. One such scoring system, Goldman's criteria (Table 8.1), assigns points to easily reproducible characteristics. The points are then added to compute the perioperative risk for cardiac-related complications. Another system, the Cardiac Risk Index, simplified this concept; it uses only six predictors to estimate cardiac complication risk in noncardiac surgical patients (Table 8.2) (Akhtar and Silverman, 2004).

TABLE 8.1

Goldman's Cardiac Risk Index

PATIENT RISK FACTORS	POINTS
Third heart sound or jugular venous distention	11
Recent myocardial infarction	10
Nonsinus rhythm or premature atrial contraction on electrocardiogram	7
More than five premature ventricular contractions	7
Age older than 70 years	5
Emergency operations	4
Poor general medical condition	3
Intrathoracic, intraperitoneal, or aortic surgery	3
Significant valvular aortic stenosis	3
For noncardiac surgery, the risk for cardiac complications is: 6–12 points = 7% risk 13–25 points = 14% risk >26 points = 78% risk	

Modified from Akhtar S, Silverman DG. Assessment and management of patients with ischemic heart disease. *Crit Care Med 2004*;32(4 Suppl):S126–S136.

TABLE 8.2

Modified Cardiac Risk Index

PATIENT RISK FACTORS	POINTS
Ischemic heart disease	11
Congestive heart failure	10
Cerebral vascular disease	7

High-risk surgery	7
Preoperative insulin treatment for diabetes	5
Preoperative creatinine ≥2 mg/dL	4
Each increment in point increases the risk for perioperative cardiovascular morbidity.	

Modified from Akhtar S, Silverman DG. Assessment and management of patients with ischemic heart disease. *Crit Care Med.* 2004;32(4 Suppl):S126–S136.

Preoperative Cardiovascular Evaluation

The preoperative cardiac evaluation, which consists of an initial history, physical examination, and ECG, attempts to identify potential serious cardiac disorders such as coronary artery disease, heart failure, symptomatic arrhythmias, the presence of a pacemaker or implantable defibrillator, or a history of orthostatic hypotension (Eagle et al., 1996, 2002). Furthermore, it is essential to define the severity and stability of existing cardiac disease before surgery. Cardiac-specific risk is also altered by the patient's functional capacity, age, and other comorbid conditions such as diabetes, peripheral vascular disease, renal dysfunction, and chronic obstructive pulmonary disease (COPD). The ACC and AHA recently collaborated to develop guidelines regarding perioperative cardiac evaluation before surgery (Fleisher et al., 2007a). In general, the guidelines use three categories of clinical risk predictors: *clinical markers*, *functional capacity*, and *type of surgical procedure* (Eagle et al., 2002).

Clinical Markers

The need for a general medical or cardiac evaluation before surgery is dependent on patients’ comorbid condition and overall perioperative risk. The *major* clinical predictors of increased perioperative cardiovascular risk includes a documented acute myocardial infarction less than 7 days previously, a recent myocardial infarction (defined as at least 7 days but less than 1 month before surgery), unstable angina, evidence of any ischemic burden by clinical symptoms or noninvasive testing, decompensated heart failure, significant arrhythmias, and severe valvular disease. *Intermediate* predictors include mild angina, previous myocardial infarction by history or pathologic Q waves on ECG, compensated heart failure, diabetes, or renal insufficiency (creatinine >2 mg/dL). *Minor* predictors of risk are advanced age, abnormal ECG, rhythms other than sinus (e.g., atrial fibrillation), history of stroke, or uncontrolled systemic hypertension. The historical dictum suggesting that elective surgery after myocardial infarction be performed after a 3- to 6-month interval is now currently avoided (Tarhan et al., 1972). **The ACC cardiovascular database committee stratifies risk on the basis of the severity of the myocardial infarction and the likelihood of reinfarction based on a recent exercise stress**

test. However, in the absence of adequate clinical trials on which to base firm recommendations, it is reasonable to wait 4 to 6 weeks after myocardial infarction to perform elective surgery, keeping in mind the kind of cardiac intervention (stents or bypass grafting) and the need for antiplatelet therapy (see later).

Functional Capacity

Functional capacity, or one's ability to meet aerobic demands for a specific activity, is quantified as metabolic equivalents of the task (METs). For example, a 4-MET demand is comparable with a patient's ability to climb two flights of stairs. This simple measurement continues to be an easy and inexpensive method to determine a patient's cardiopulmonary functional capacity (Biccard, 2005). **The Duke Activity Status Index (Table 8.3), which has been validated in several studies, allows the physician to easily determine a patient's functional capacity** (Hlatky et al., 1989; Carter et al., 2002; Coutinho-Myrrha et al., 2014; Wu et al., 2016). **In general, a capacity of 4 METs indicates no further need for invasive cardiac evaluation.**

TABLE 8.3

Duke Activity Status Index[a]

ACTIVITY	YES	NO
Can you take care of yourself such as eating, dressing, bathing, or using the toilet?	2.75	0
Can you walk indoors such as around your house?	1.75	0
Can you walk a block or two on level ground?	2.75	0
Can you climb a flight of stairs or walk up a hill?	5.50	0
Can you run a short distance?	8.00	0
Can you do light work around the house such as dusting or washing dishes?	2.70	0
Can you do moderate work around the house such as vacuuming, sweeping floors, or carrying in groceries?	3.50	0
Can you do heavy work around the house such as scrubbing floors or lifting and moving heavy furniture?	8.00	0
Can you do yardwork such as raking leaves, weeding, or pushing a power mower?	4.50	0
Can you have sexual relations?	5.25	0
Can you participate in moderate recreational activities such as golf, bowling, dancing, doubles tennis, or throwing a baseball or football?	6.00	0

Can you participate in strenuous sports such as swimming, singles tennis, football, basketball, or skiing?	7.50	0

[a] The most widely recognized measure of cardiorespiratory fitness is maximal oxygen consumption (VO_2peak) measured in mL/kg/min. The Index score correlates directly with VO_2peak and therefore is an indirect measure of maximal METs.

Duke activity status index (DASI) = Sum of values for all 12 questions

Estimated peak oxygen uptake (VO_2peak) in mL/min = (0.43 × DASI) + 9.6

METs (metabolic equivalents of the task) = VO_2peak × 0.286 $(\text{mL/kg/min})^{-1}$

Modified from Hlatky MA, Boineau RE, Higginbotham MB, et al. A brief self-administered questionnaire to determine functional capacity (the Duke Activity Status Index). *Am J Cardiol.* 1989;64(10):651–654.

Surgery-Specific Cardiac Risk

Two important factors determine the surgery-specific cardiac risk: the type of surgery and the degree of hemodynamic stress. Surgery-specific risk is stratified into high-, intermediate-, and low-risk procedures. High-risk procedures include both major emergent surgeries, particularly in the elderly, and surgery associated with increased operative time resulting in large fluid shifts or blood loss. Intermediate risk procedures include intraperitoneal surgery, laparoscopic procedures, and robotic-assisted laparoscopic surgeries. Low-risk procedures include endoscopic procedures or superficial surgeries (i.e., not involving entrance into a body cavity) (Eagle et al., 2002).

Pulmonary Evaluation

Preoperative pulmonary evaluation is important in all urologic procedures but critical in those surgeries involving the thoracic or abdominal cavities. These procedures, which include intra-abdominal, laparoscopic, or robotic surgeries, can decrease pulmonary function during the operation or postoperatively and predispose to pulmonary complications. Accordingly, it is prudent to consider pulmonary functional assessment in patients who have significant underlying pulmonary disorder, significant smoking history, or overt pulmonary symptoms. Pulmonary function tests that include a forced expiratory volume in 1 second (FEV_1), forced vital capacity, and the diffusing capacity of carbon monoxide are quite easily performed and provide a preoperative baseline. **Patients with an FEV_1 of less than 0.8 L/sec or 30% of predicted are at high risk for complications** (Arozullah et al., 2003). Specific pulmonary risk factors include COPD, smoking, preoperative sputum production, pneumonia, dyspnea, and obstructive sleep apnea. **It has been shown that smokers have a fourfold increased risk for postoperative pulmonary morbidity and as high as a 10-fold higher mortality rate** (Fowkes et al., 1982). In general, it is interesting to note that patients with restrictive pulmonary disease fare better than those with obstructive pulmonary disease because the former group maintains an adequate maximal expiratory flow rate, which allows for a more effective cough with less sputum production (Pearce and Jones, 1984). In addition to the specific pulmonary risk factors, general factors contribute to increased pulmonary complications such as increased age, lower serum albumin levels, obesity, impaired sensorium, previous stroke, immobility, acute renal failure, and chronic steroid use.

Hepatobiliary Evaluation

Survival of patients with advanced liver disease has improved over the past decade, thus surgery is being performed more frequently in these patients. Furthermore, patients with mild to moderate hepatic disease are often asymptomatic. These patients need to be identified and evaluated before surgery. Patients are usually aware of a prior diagnosis of hepatitis, and they should be questioned regarding the timing of diagnosis and the precipitating factors. This history is particularly important if a member of the health care team is inadvertently stuck with a needle or cut with a scalpel during the surgical procedure. A review of systems should include questions regarding pruritus, excessive bleeding, abnormal abdominal distention, and weight gain. On physical examination, jaundice and scleral icterus may be evident with serum bilirubin levels higher than 3 mg/dL. Skin changes such as caput medusae, palmar erythema, spider angiomas, and clubbing all indicate hepatic dysfunction. Severe manifestations include abdominal distention, encephalopathy, asterixis, or cachexia. Again, identification of underlying hepatic illness is important in the preoperative risk assessment of the patient. Although the estimation of perioperative mortality is limited by the lack of high-quality clinical studies, the use of the Child classification and model for end-stage liver disease (MELD) score offers a reasonable estimation.

The Child classification assesses perioperative morbidity and mortality in patients with cirrhosis and is based on the patient's serum markers (bilirubin, albumin, PT) and severity of clinical manifestations (i.e., encephalopathy and ascites). **Mortality risk for patients undergoing surgery stratified by Child class is as follows: Child Class A—10%, Child Class B—30%, and Child Class C—76% to 82%.** The Child classification also correlates with the frequency of complications such as liver failure, encephalopathy, bleeding, infection, renal failure, hypoxia, and intractable ascites. Independent risk factors other than the Child class that can increase the mortality rate in patients with liver disease include emergency surgery and COPD (Pearce and Jones, 1984; O'Leary et al., 2009; O'Leary and Friedman, 2007).

The MELD score is perhaps a more accurate assessment of perioperative mortality in patients with hepatic dysfunction. The score is derived from a linear regression model based on serum bilirubin, creatinine levels, and the INR. It is more accurate than the Child classification in that it is objective, gives weights to each variable, and does not rely on arbitrary cutoff values (Teh et al., 2007). **Clinicians can use a website (http://mayoclinic.org/meld/mayomodel9.html) to calculate the 7-day, 30-day, 90-day, 1-year, and 5-year surgical mortality risk on the basis of the patient's age, ASA class, INR, serum bilirubin, and creatinine levels.** A recent study also found that the MELD score was tightly correlated with 30-day mortality risk in all patients undergoing colorectal surgery regardless of the presence of liver disease (Hedrick et al., 2013). Taken together, the Child classification and the MELD score complement each other and provide an important assessment of the risk associated with surgery in cirrhotic patients (O'Leary and Friedman, 2007; O'Leary et al., 2009).

Special Populations

Elderly

It is estimated that by 2050 the number of Americans older than 65 years of age will more than double to 89 million individuals, with more than 20% older than 85 years of age (Jacobson et al., 2011). Accordingly, octogenarians and nonagenarians are undergoing an increasing number of surgeries annually. Because of elderly patients' special physiologic, pharmacologic, and psychological needs, a unique set of health care challenges is encountered. It is still unclear whether advanced age independently predicts surgical risk or whether it is coexisting medical conditions that adversely affect surgical outcomes. However, in a large study published by Turrentine, the authors showed that increased age independently predicted morbidity and mortality (Turrentine et al., 2006). This confirmed the study by Vemuri, who also found increased age to be an independent risk factor for morbidity and mortality in patients undergoing aneurysm surgery (Vemuri et al., 2004). Within the urologic literature, Liberman et al. reported 90-day mortality rates after radical cystectomy in patients younger than 70 years, 70 to 80 years, and older than 80 years of 2%, 5.4%, and 9.2%, respectively (Liberman et al., 2011). The studies suggest that independent of comorbidities, perhaps the elderly patient cannot meet the increased functional demand required during the perioperative and postoperative periods. Notably, hypertension and dyspnea were the most frequently seen comorbid risk factors in patients older than 80 years of age, and preoperative transfusion history, emergency operation, and weight loss best predicted postoperative morbidity. Additionally, each 30-minute increment of operative time increased the odds of mortality by 17% in octogenarians (Turrentine et al., 2006). A unique and important factor in the perioperative care of the elderly is in the identification and prevention of delirium. Often overlooked as "sundowning," delirium can be the first clinical sign of metabolic and infectious complications (Townsend et al., 2015).

Morbid Obesity

The careful selection of the morbidly obese patient for elective surgery is of paramount importance. With the rising incidence of obesity, one must carefully weigh and balance the risk associated with any surgical procedure with the natural history of the disease when deciding the optimal time of the surgery in the morbidly obese. **It is estimated that patients with a body mass index (BMI) of 45 kg/m^2 or higher may lose anywhere from 8 to 13 years of life expectancy** (Fontaine et al., 2003). Cardiac symptoms such as exertional dyspnea and lower extremity edema are nonspecific in morbidly obese patients, and many of these patients have poor functional capacity. The physical examination often underestimates cardiac dysfunction in the severely obese patient. Severely obese patients with more than three coronary heart disease risk factors may require noninvasive cardiac evaluation (Poirier et al., 2009). Obesity is associated with a vast array of comorbidities. Morbidly obese patients often have atherosclerotic cardiovascular disease, heart failure, systemic hypertension, pulmonary hypertension related to sleep apnea and obesity, hypoventilation, cardiac arrhythmias, deep vein thrombosis, history of pulmonary embolism, and poor exercise capacity. There are also numerous pulmonary abnormalities that result in a ventilation perfusion mismatch and alveolar hypoventilation. Obesity is a risk factor for postoperative wound infections, and, when appropriate, laparoscopic surgery should be considered.

Pregnancy

Urologic surgery in the pregnant woman is most commonly related to the management of renal colic and urinary tract stones. The stones can be discovered during the sonographic evaluation of the fetus in an asymptomatic pregnant woman or during the evaluation of the pregnant woman who is experiencing renal colic. **The fetus is at the highest risk from radiation exposure from the preimplantation period to approximately 15 weeks' gestation.** Because the radiation dose that is associated with congenital malformations is 10 cGy, the evaluation of renal colic in the pregnant patient is performed usually with sonography (radiation dose with abdominal computed tomography [CT]—1 cGy; intravenous pyelogram—0.3 cGy). **In general, a surgical procedure in the pregnant woman should be delayed, if at all possible, until the baby is mature enough for delivery unless significant harm to the mother or fetus will result.** The indications for operative intervention in the pregnant patient are discussed elsewhere in this book. Anesthetic risks during pregnancy concern both the mother and the fetus. During the first trimester, the fetus may be directly exposed to the teratogenic effects of certain anesthetic agents. Later in pregnancy, anesthesia places the mother at risk for preterm labor and the fetus at risk for hypoxemia secondary to changes in uterine blood flow and maternal acid-base imbalance. These risks seem to be greatest during the first and third trimesters. **For semi-elective procedures, an attempt should be made to delay surgery until after the first trimester.** However, one must consider the continued exposure of the underlying condition in relation to the operative risks to both the mother and fetus. **The second trimester is the safest time to perform surgery because organ system differentiation has occurred and there is almost no risk for anesthetic-induced malformation or spontaneous abortion.** When one is contemplating surgery on a pregnant patient, consultation with the obstetrician, perinatologist, and anesthesiologist is essential (Kizer and Powell, 2011). These specialists will help determine the optimum technique to monitor the status of the fetus. Fetal heart rate monitors and tocometer monitoring for uterine activity are used before and after the procedure. Postoperative pain is best managed with narcotic analgesics because they have not been shown to cause birth defects in humans when used in normal dosages. Nonsteroidal anti-inflammatory medication should be avoided because of the risk for premature closure of the ductus arteriosus. Chronic use of narcotics during pregnancy may cause fetal dependency, and it is recommended that the pregnant postsurgical patient be weaned off narcotic use as soon as possible.

Nutritional Status

Malnutrition compromises host defenses and increases the risk for perioperative morbidity and mortality. Adequate nutritional status is essential for proper wound healing, mounting appropriate immune response to infections, return of bowel activity, and maintenance of vital organ function (Evans et al., 2014). The preoperative evaluation and classification of the patient's nutritional status typically consist of assessment of any recent weight loss and measurement of laboratory values, such as lymphocyte count and serum albumin. A 20-pound weight loss in the preceding 3 months before surgery is considered to be a reflection of severe malnutrition. The lymphocyte count and serum albumin level reflect visceral protein status, with lower levels indicating malnutrition (Reinhardt et al., 1980). Several assessment tools have been validated to quantitate nutritional status, including the Subjective Global Assessment (http://subjectiveglobalassessment.com).

There are two methods for nutritional support. **Total parenteral nutrition**

(TPN) is used for patients who are severely malnourished and who have a nonfunctioning gastrointestinal (GI) tract. Several studies have shown that 7 to 10 days of preoperative parenteral nutrition improves postoperative outcome in undernourished patients (Von Meyenfeldt et al., 1992). However, its use in well-nourished or mildly undernourished patients either is of no benefit or increases the risk for sepsis (Veterans Affairs Total Parenteral Nutrition Cooperative Study Group, 1991). **Enteral nutrition,** on the other hand, has fewer complications than TPN and can provide a more balanced physiologic diet. Enteral nutrition is accomplished via a feeding tube, gastrostomy, or feeding jejunostomy. Enteral nutrition has the added benefits of maintaining the gut-associated lymphoid tissue, enhancing mucosal blood flow, and maintaining the mucosal barrier. There are hundreds of enteral products on the market, and most have a caloric density of 1 to 2 kcal/mL. These formulas are also lactose free and provide the recommended daily allowances of vitamins and minerals in less than 2 L/day. Patients receiving enteral feedings must be monitored for improvement in nutritional status, GI intolerance, and fluid and electrolyte imbalance. **Preoperative enteral feedings can decrease postoperative complication rates by 10% to 15% when used for 5 to 20 days before surgery** (ASPEN Board of Directors and the Clinical Guidelines Task Force, 2002). **The guidelines recommend postoperative parenteral nutrition in patients who are unable to meet their caloric requirements within 7 to 10 days.** Just as in the perioperative state, enteral feedings are preferred over parenteral nutrition when feasible (Sigalet et al., 2004). Moreover, the routine use of postoperative TPN has not proven useful in well-nourished patients or in those with adequate oral intake within 1 week after surgery.

Complications can occur with either enteral nutrition or parenteral nutrition. Dislodgement of nasoenteral tubes and percutaneous enteral catheters can result in pulmonary and peritoneal complications. Adynamic ileus may also occur because of decreased splanchnic perfusion, sympathetic tone, or opiate use. With regard to TPN, establishing central access is associated with a significant risk for complications. These include pneumothorax or hemothorax secondary to poor line placement and chylothorax secondary to thoracic duct injury. Line sepsis is the most common complication of indwelling central catheters and necessitates catheter removal. Venous thrombosis with associated thrombophlebitis and extremity edema has been reported. Catheter thrombosis has also been reported and can be treated with thrombolytic agents (ASPEN Board of Directors and the Clinical Guidelines Task Force, 2002).

Preparation for Surgery

Management of Medications

Preoperative Optimization Strategies

Optimization of Comorbid Illness.

Just as adequate preoperative evaluation is important, optimization of comorbid illness is critical in improving surgical outcomes and in reducing perioperative morbidity and mortality. With regard to cardiac disease, many studies have evaluated the prophylactic use of nitrates, calcium-channel blockers, and β-blockers for patients who are at risk for perioperative myocardial ischemia. Only β-blockade has been shown to improve outcomes (Pearse et al., 2004). In a landmark study, Mangano et al. reported that there was an improvement in outcomes with the prophylactic use of atenolol in patients undergoing vascular surgery (Mangano et al., 1996). Similarly, a retrospective, cooperative group study of more than one-half million patients showed that perioperative β-blockade is associated with a reduced risk for death among high-risk patients undergoing major noncardiac surgery (Lindenauer et al., 2005). In addition to β-blockade, the concept of goal-directed therapy, employing the judicious use of fluids, inotropes, and oxygen therapy to achieve therapeutic goals may further reduce perioperative risk (Pearse et al., 2004). This concept was validated by Shoemaker, who reported an impressive reduction in mortality from 28% to 4% ($P < .02$) when goal-directed therapy was used (Shoemaker et al., 1988).

Specific preoperative interventions can decrease pulmonary complications. **Smoking must be discontinued at least 8 weeks before surgery to achieve a risk reduction.** Patients who discontinue smoking less than 8 weeks before surgery may actually have a higher risk for complications because the acute absence of the noxious effect of cigarette smoke decreases postoperative coughing and pulmonary toilet (Pearce and Jones, 1984). **However, patients who stop smoking at least 8 weeks preoperatively will significantly lower their complication rate, and patients who have ceased smoking for more than 6 months have a pulmonary morbidity comparable with that of nonsmokers** (Warner et al., 1989). The use of preoperative bronchodilators in COPD patients can dramatically reduce postoperative pulmonary complications. Aggressive treatment of preexisting pulmonary infections with antibiotics and the pretreatment of asthmatic patients with steroids are essential in optimizing pulmonary performance. Likewise, the use of epidural and regional anesthetics, vigorous pulmonary toilet, rehabilitation, and continued bronchodilation therapy is all beneficial (Arozullah et al., 2003).

As with cardiopulmonary comorbidities, the preoperative management and optimization of diabetic patients are quite important. Perioperative hyperglycemia can lead to impaired wound healing and a higher incidence of infection (Golden et al., 1999). Hypoglycemia in an anesthetized or sedated diabetic patient may be unrecognized and carries its own significant risks. **Non–insulin-dependent diabetic patients may need to discontinue long-acting hypoglycemics because of this risk for intraoperative hypoglycemia. Shorter-acting agents or sliding-scale insulin regimens are preferable, in general.** It is recommended that blood glucose levels be controlled between 80 and 250 mg/dL. Frequent fingerstick glucose checks and a sliding scale short-acting insulin regimen are used in the postoperative period. Once the patient is eating, the usual insulin regimen can be resumed. Patients who manage their diabetes with the use of insulin pumps should continue their basal insulin infusions on the day of surgery. The pump is then used to correct the glucose level as it is measured. It is important to know the sensitivity factor that corrects the glucose so that the patient's sugars can be managed in the operating room (Townsend et al., 2015).

Patients with either hyperthyroidism or hypothyroidism should be evaluated by an endocrinologist, and surgery should be deferred until a euthyroid state has been achieved. **The greatest risk in the hypothyroid patient is thyrotoxicosis, or thyroid storm, which can manifest with fevers, tachycardia, confusion, and cardiovascular collapse.** Atrial fibrillation may also be present in 20% of hyperthyroid patients (Klein and Ojamaa, 2001). With regard to hyperthyroidism, careful attention should be given to the airway because the trachea can be compressed or deviated by a large goiter. In general, antithyroid medications such as propylthiouracil or methimazole, as well as β-blockers, are continued on the day of surgery. In the event of thyroid storm, iodine and steroids may be necessary (Schiff and Welsh, 2003). Hypothyroidism is usually associated with an increased sensitivity to medications such as anesthetic agents and narcotics. Severe hypothyroidism can be associated with myocardial dysfunction, coagulopathy, electrolyte imbalance, and a decreased GI motility. Symptoms include lethargy, cold intolerance, hoarseness, constipation, dry skin, and apathy. The decrease in metabolic rate produces periorbital edema, thinning of the eyebrows, brittle hair, dry skin, hypothermia, bradycardia, and a prolonged relaxation of the deep tendon reflexes (Murkin, 1982). Once the diagnosis has been confirmed by a low thyroxine level and an elevated thyroid stimulating hormone level, thyroid replacement with levothyroxine can be initiated (Schiff and Welsh, 2003).

The evaluation of the patient either taking corticosteroids or suspected of having an abnormal response of the hypothalamic-pituitary-adrenal (HPA) axis is also important. There is a wide variability in HPA suppression in patients receiving exogenous steroids. Nonetheless, it seems clear that the administration of oral steroids equivalent to less than 5 mg of prednisone for any duration of time does not cause clinically significant suppression of the HPA axis. **By contrast, any patient taking more than 20 mg of prednisone or its equivalent per day for more than 3 weeks or who is clinically cushingoid has probable HPA axis suppression** (LaRochelle et al., 1993). HPA suppression can occur even in patients using potent topical steroids at doses of 2 g/day and in patients using inhaled corticosteroids at doses of 0.8 mg/day. Although the duration of functional HPA axis suppression after glucocorticoids have been stopped is debatable, perioperative supplemental steroids are recommended for patients who have received HPA axis–suppressive doses within 1 year of surgery. A low-dose adrenocorticotropic hormone (ACTH) stimulation test can be used to assess the HPA axis and the need for stress steroids. For patients who take 5 mg of prednisone or the equivalent each day, no supplemental steroids are necessary, and the usual daily glucocorticoid dose may be given in the perioperative period. **For those in whom the HPA axis is presumed to be suppressed or is documented to be suppressed, then 50 to 100 mg of intravenous hydrocortisone is given before the induction of anesthesia, and 25 to 50 mg of hydrocortisone is given every 8 hours thereafter for 24 to 48 hours until the usual steroid dose can be resumed.** Minor procedures under local anesthesia do not require stress-dose steroids (Schiff and Welsh, 2003).

Antithrombotic Therapy

Most urologic patients have medical comorbidities; urologists frequently encounter patients on chronic vitamin K antagonist therapy (e.g., warfarin) or antiplatelet therapy for the management of atrial fibrillation, mechanical heart valves, or coronary artery disease. Perioperative management including interruption of this antithrombotic therapy can be a challenging problem. Unlike venous thromboembolism (VTE) pharmacologic prophylaxis, warfarin and antiplatelet therapies have been shown to be associated with significant bleeding complications after surgery. Therefore, urologists must carefully consider and balance the risks and benefits of interruption of chronic anticoagulation to determine the best course of perioperative management of these medications.

Chronic anticoagulation with warfarin is most frequently encountered in patients with atrial fibrillation, mechanical heart valves, or prior VTE. **The pharmacologic half-life of warfarin is 36 to 42 hours, and therefore most guidelines recommend cessation of therapy 5 days before surgery to ensure an INR less than 1.5.** Recently, several new oral anticoagulants (e.g., apixaban, dabigatran, and rivaroxaban), have been introduced to improve efficacy, decrease patient variability, and improve patient convenience. Each of the new medications has different pharmacologic properties, and therefore it is imperative for the surgeon to be familiar with these medications to properly advise the patient (Douketis et al., 2012; Douketis, 2010). The larger issue is whether patients require a bridge with short-term anticoagulation between the time of subtherapeutic INR and surgery. The decision is based on risk for a thrombotic event. Regarding atrial fibrillation, clinical scoring systems such as congestive heart failure, hypertension, age, diabetes, stroke (CHADS2) stratify patients into risk groups that predict risk for stroke while patients are not undergoing anticoagulation therapy. Patients with mechanical heart valves can also be stratified into risk groups according to the location (mitral vs. aortic) and type of valve used. Similarly, patients with a prior history of VTE are stratified according to duration since the last VTE and the patient's risk for recurrent VTE (Table 8.4). **In general, the 2012 American College of Chest Physicians (ACCP) guidelines recommends that patients in the moderate- and high-risk groups undergo bridging anticoagulation with therapeutic-dose subcutaneous low–molecular-weight heparin or intravenous unfractionated heparin** (Douketis et al., 2012).

TABLE 8.4

Risk Stratification for Arterial or Venous Thromboembolism Events During Perioperative Period in Patients on Chronic Anticoagulant Therapy

RISK	INDICATIONS FOR ANTICOAGULANT THERAPY

STRATUM	MECHANICAL HEART VALVE	ATRIAL FIBRILLATION	VTE
Low	Bileaflet aortic valve prosthesis without atrial fibrillation and no other risk factors for stroke	CHADS2 score of 0–2 (and no prior stroke or transient ischemic attack)	Single VTE occurred >12 mo ago and no other risk factors
Moderate	Bileaflet aortic valve prosthesis plus one or more of the following: atrial fibrillation, prior stroke or transient ischemic attack, hypertension, diabetes, congestive heart failure, age above 75 yr	CHADS2 score of 3–4	VTE within the past 3–12 mo Nonsevere thrombophilic conditions (e.g., heterozygous factor V Leiden mutation, heterozygous factor II mutation) Recurrent VTE Active cancer (treated within 6 mo or palliative)
High	Any mitral valve prosthesis Any caged-ball or tilting disc aortic valve prosthesis Recent (within 6 mo) stroke or transient ischemic attack	CHADS2 score of 5–6 Recent (within 3 mo) stroke or transient ischemic attack Rheumatic valvular heart disease	Recent (within 3 mo) VTE Severe thrombophilia (e.g., deficiency of protein C, protein S, or antithrombin; presence of antiphospholipid antibodies; multiple abnormalities)

CHADS2, Congestive heart failure, hypertension, age, diabetes, stroke; *mo,* months; *VTE,* venous thromboembolism; *yr,* year.

Modified from Douketis JD, Spyropoulos AC, Spencer FA, et al. Perioperative management of antithrombotic therapy: Antithrombotic Therapy and Prevention of Thrombosis, 9th ed: American College of Chest Physicians evidence-based clinical practice guidelines. *Chest.* 2012;141(2 Suppl):e326S–e350S.

An increasing number of patients are receiving chronic antiplatelet therapy in the prevention of cardiovascular events and, more important, in the prevention of coronary stent thrombosis. Although the former indication poses little controversy for the urologist, the latter indication presents a significant and complex clinical challenge in which the urologist must weigh the risk for bleeding with the potentially devastating risk for perioperative stent thrombosis. Aspirin and clopidogrel are the two most commonly used antiplatelet drugs and are frequently used together. Both are irreversible inhibitors of platelet function and therefore need to be stopped 7 to 10 days before surgery to minimize bleeding risk. **Current recommendations require dual antiplatelet therapy for 6 weeks after bare metal coronary stents and 12 months for drug-eluting stents. Premature interruption of antiplatelet therapy has been associated with a 25% to 50% risk for significant myocardial infarction with resultant increased perioperative mortality** (O'Riordan et al., 2009). In most patients, urologists should defer elective surgery until after antiplatelet therapy can be safely interrupted. In a review of the literature, Gupta et al. recommended delay of elective urologic surgery for at least 30 days for bare metal stents and, if possible, longer than 1 year for drug-eluting stents (Gupta et al., 2012). Even then, because acute stent thrombosis has been described with drug-eluting stents after 12 months, urologists should strongly consider at least single-agent antiplatelet therapy in these patients. Given the current lack of clinically useful alternatives to antiplatelet therapy, when surgery cannot be delayed (e.g., because of malignancy), the ACCP strongly recommends continuing aspirin and clopidogrel during the perioperative period in patients with drug-eluting stents (Douketis et al., 2012). Nevertheless, communication between the urologist and the cardiologist throughout the perioperative period is essential to minimize complications and maximize outcomes.

Bowel Preparation

Since antibiotics were first shown to reduce infectious complications in GI surgery, mechanical and antibiotic bowel preparation has been a mainstay of urologic surgery employing intestinal segments. The rationale for bowel preparation before intestinal surgery is to decrease intraluminal feces and decrease bacterial colony counts to decrease the rate of anastomotic leak, intra-abdominal abscesses, and wound infections. The bacterial flora in the bowel consists of aerobic organisms, the most common of which are *Escherichia coli* and *Enterococcus faecalis*, and anaerobic organisms, the most common of which are *Bacteroides* species and *Clostridium* species. **The bacterial concentration**

ranges from 10 to 10^5 organisms per gram of fecal content in the jejunum, 10^5 to 10^7 in the distal ileum, 10^6 to 10^8 in the ascending colon, and 10^{10} to 10^{12} in the descending colon. The preparation itself consists of two components: antibiotic preparation and mechanical preparation. Because there are only a few small series in the urologic literature, the rationale for each must be inferred from the general surgery literature—specifically, from colorectal surgery literature.

Although preoperative parenteral antibiotic prophylaxis before intestinal surgery is well established and widely used, oral antibiotic preparation is still somewhat controversial. Several oral antibiotic regimens are used today. The most commonly used regimen, oral neomycin and erythromycin, first became established in 1977 with the landmark study by Clark et al. (Clarke et al., 1977). In a double-blind, placebo-controlled study, 167 patients undergoing elective colonic surgery were randomized to receive mechanical bowel preparation with or without oral neomycin and erythromycin. The overall rates of septic complications were 43% with mechanical-only preparation and 9% with antibiotic plus mechanical preparation ($P = .001$). However, with current standards of the use of preoperative *parenteral* antibiotics, the benefit of oral antibiotic preparation was debated. Several older studies reported decreased infectious complications; however, these studies were small, and there have been no randomized controlled trials (RCTs) to document the benefit. **The disadvantage of oral antibiotic preparation is primarily related to increased incidence of pseudomembranous colitis secondary to *Clostridium difficile* infection.** In a retrospective analysis of 304 patients, Wren et al. reported a significantly decreased incidence of *C. difficile* colitis in patients who did not receive oral antibiotics before elective colorectal surgery (2.6% vs. 7.2%, $P = .03$) (Wren et al., 2005). Inferring from the colorectal literature, most current guidelines and a 2014 Cochrane review recommend that **antibiotics covering aerobic and anaerobic bacteria delivered orally or intravenously (or both) before elective colorectal surgery reduce the risk for surgical wound infection by as much as 75%** (Nelson et al., 2014). Despite the lack of level 1 evidence in the literature, a recent survey of colorectal surgeons revealed that up to 87% of surgeons continue to administer oral antibiotic bowel preparation before elective surgery (Zmora et al., 2003). In the 2014 Cochrane review, however, it was acknowledged that it is unknown whether oral antibiotics would have any beneficial effect in reducing surgical wound infection when the colon is not empty (Nelson et al., 2014).

Mechanical bowel preparation predates the use of antibiotics in intestinal surgery and was thought to decrease the rate of anastomotic complications. Before the development of nonabsorbable liquids, patients underwent several days of oral laxatives, bowel irrigations via nasogastric tubes, and repeat enemas. These regimens were associated with significant patient discomfort and clinical morbidity caused by electrolyte imbalances. The development of polyethylene glycol solution (GoLYTELY) and sodium phosphate solution (Fleet Phospho-soda) reduced much of the electrolyte disturbance and allowed for mechanical bowel preparation to be done in the outpatient setting. **Both regimens are suitable for most patients; however, polyethylene glycol is preferred in the elderly and in patients with renal insufficiency, congestive heart failure, existing electrolyte disturbances, and cirrhosis because it is completely nonabsorbable.**

The benefit of mechanical bowel preparation has been assumed for decades as evidenced by 99% positive response by colorectal surgeons when asked if mechanical preparation is routinely used (Zmora et al., 2003). However, RCTs have called into doubt the true benefit. Slim et al. published a meta-analysis of RCTs including a total of 4859 patients (Slim et al., 2009). The analysis included 14 trials including two large trials from the Netherlands and Sweden (Contant et al., 2007; Jung et al., 2007). **Overall, the analysis revealed that mechanical bowel preparation provided no benefit for anastomotic leak (odds ratio [OR] 1.12, 95% confidence interval [CI], 0.82 to 1.53, *P* = .46); abdominal or pelvic abscess (OR 0.90, 95% CI 0.47 to 1.72, *P* = .75); or mortality (OR 0.91, 95% CI 0.57 to 1.45, *P* = .70).** In fact, when overall surgical site infection (SSI) was considered, mechanical bowel preparation was associated with a significantly increased risk (OR 1.40, 95% CI 1.05 to 1.87, *P* = .02). These results were reiterated in an updated Cochrane review, which found no significant differences in anastomotic leak rate or wound infection, need for reoperation, and mortality rates (Güenaga et al., 2011). The authors concluded that there was no evidence that mechanical bowel preparation improves patient outcomes after elective colorectal surgery. Although similar studies have not been done in patients undergoing elective urologic surgery, urologists can make inferences from the colorectal literature and should reevaluate the common practice of mechanical bowel preparation before urologic intestinal surgery. To date, there have been multiple single-institution reports suggesting equivalent SSI outcomes with or without bowel preparation before radical cystectomy and urinary diversion (Zaid et al., 2013). Two specific exceptions are transrectal ultrasound-guided prostate needle biopsy and laparoscopic urologic surgery. Given the portal of entry and subsequent risk for bacteremia, most urologists have advocated for mechanical rectal cleansing with an enema before transrectal ultrasound-guided prostate needle biopsy. With regard to laparoscopy, surgeons who perform minimally invasive procedures have long believed that preoperative bowel preparation improves operative exposure because of bowel decompression and decreases the incidence of postoperative ileus. However, to date there have been no trials to support this assertion.

In the early postoperative period, most patients experience some degree of primary ileus and delayed GI activity. Any patient with ileus lasting more than 72 to 96 hours after surgery should be evaluated for a mechanical bowel obstruction secondary to adhesions, an intra-abdominal pathologic process, or a retroperitoneal hemorrhage. Given that return of GI function is often the rate-limiting factor for hospital discharge, efforts to reduce ileus including minimization of parenteral or oral opioid use, selective use of nasogastric tubes, and correction of electrolyte imbalances should be employed. More recently, methods to accelerate GI recovery have been investigated. Gum chewing—that is, sham feeding—was evaluated and reported to be associated with improvements in GI recovery and reduction in length of stay in patients undergoing colorectal surgery (Ho et al., 2014). Alvimopan (Entereg) is a peripherally acting opioid antagonist that was approved by the U.S. Food and Drug Administration (FDA) in 2008 to help restore bowel function after surgery. With the validation of alvimopan established in the colorectal literature, there have been several studies performed in patients undergoing cystectomy including a phase 4 trial whose findings were recently published. Use of alvimopan compared with placebo resulted in decreased length of stay of 2.6 days in patients undergoing radical cystectomy (Kauf et al., 2014). Many high-volume centers are now incorporating both strategies into enhanced recovery after surgery (ERAS) clinical pathways to reduce postoperative ileus and reduce hospital stays.

Intraoperative Management

Patient Environment

Maintaining an optimal patient environment is critical for the overall outcome of the patient. Although hypothermia can be therapeutic in certain situations of trauma and brain injury, for elective surgical procedures, hypothermia is associated with significantly increased morbidity to the patient. **There are two primary reasons for hypothermia to develop in the operating room. Anesthetic agents induce peripheral vasodilation, redistributing heat from the core (trunk, head) with a resultant drop in immediate core temperature after induction. Throughout the rest of the surgical procedure, radiation and conductive heat loss account for most of the heat loss.** *Normothermia* is defined as a core temperature between 36°C and 38°C, and hypothermia of even 1°C to 2°C results in adverse effects. **Rajagopalan et al. performed a meta-analysis of RCTs and reported that mild hypothermia (decrease of 1°C) resulted in a 16% increase in estimated blood loss and a 22% increase in transfusion requirements** (Rajagopalan et al., 2008). The increased bleeding risk is thought to result from a hypothermia-associated decrease in clotting cascade enzymatic function and platelet aggregation. Even more significant is the increase in the risk for SSI associated with mild hypothermia (34°C to 36°C). Hypothermia increases the risk for SSI by impairing immune mechanisms and vasoconstriction, resulting in regional tissue hypoxia. In a landmark study, Kurz et al. with the Study of Wound Infection and Temperature Group tested in 200 patients undergoing elective colorectal surgery the hypothesis that hypothermia increases the rate of wound infection and hospital stay (Kurz et al., 1996). **Hypothermia was associated with a three times increased risk for wound infection and a 2.6-day increase in hospitalization.** More recent studies have confirmed these findings in general in other series of surgical patients (Mauermann and Nemergut, 2006). In its overall goal of reducing SSI, the SCIP has also included perioperative normothermia as one of its guidelines. Strategies to improve maintenance of normothermia include regular use of warming blankets, warmed intravenous fluids, warmed irrigation fluids (especially during transurethral resection of the prostate [TURP] and other prolonged endoscopic procedures), warmed humidified CO_2 gas during laparoscopy, and increase in ambient operating room temperature. Although there have been few studies in the urologic literature, the findings can be generalized to all surgical patients.

Patient Safety

In 1991, Brennan et al. published their seminal work describing adverse events, defined as injuries caused by medical management in hospitalized patients, revealing that 48% of the events accompanied a surgical operation (Brennan et al., 1991; Leape et al., 1991). This important study inspired the publication of “To Err Is Human: Building a Safer Health System,” a comprehensive study by the Institute of Medicine on medical errors. Regarding surgical patients, the most frequent venue of preventable injuries is the operating room. **Although the surgeon is the “captain of the ship” and ultimately responsible, it takes cognizance and attention to detail from each member of the operating room team to prevent iatrogenic injuries to the patient.** Three causes of immediately preventable injuries are retractor-associated injuries, thermal injuries, and patient position–related injuries. There are several reports in the literature documenting an increased rate of neuropathy (especially femoral nerve) after laparotomy with self-retaining retractors versus without self-retaining retractors (Irvin et al., 2004). Careful attention to be certain that the lateral blades do not directly compress the psoas muscle and only cradle the rectus abdominal muscles will ensure avoidance of femoral neuropathy. Furthermore, periodic reinspection of the retractor blades is also warranted. Many devices used in urologic surgery employ thermal energy for desired effect and therefore can result in thermal injury to the patient. These include Bovie cautery, the argon beam coagulator, bipolar devices, and lasers. In both endoscopic and laparoscopic surgery, high-wattage light sources are used to illuminate the operative field. Although it is illuminated, the ends of the light cords can result in burns when in direct contact with the patient (even through draping). These light sources should be turned off or placed on standby at all times when not in use. Special mention is deserved for the morbidly obese patient. The operating room should be equipped with a hydraulic table, extra-long instruments, additional padding, wide venous compression devices, and side extensions to the operating table to ensure a safe operating room environment for the patient.

Patient Positioning

Although often given only a cursory evaluation, proper patient positioning in the operating room can prevent potentially devastating complications. Ultimately, proper positioning is the shared responsibility of each member of the operating room team. Much of the knowledge and guidelines for avoidance of position-related injury are drawn from the anesthesia literature. In fact, based on a 1999 study of the ASA Closed Claims Database, which found neuropathy as second-leading cause of liability, the ASA published a practice advisory for the prevention of perioperative peripheral neuropathies (American Society of Anesthesiologists, 2018). The recommendations are listed in Box 8.2. **Although the exact mechanisms of peripheral neuropathy are not always known, the cause of position-related neuropathy is usually secondary to excessive stretch, prolonged compression, or ischemia.** Given the variety of different patient positions used in urologic surgery, it is critical for the urologist to be an active participant in the positioning of the patient and to understand the potential patient compromise that accompanies each position.

Box 8.2

American Society of Anesthesiologists Task Force Recommendations on the Prevention of Perioperative Peripheral Neuropathies

Preoperative Assessment

- When judged appropriately, it is helpful to ascertain that patients can comfortably tolerate the anticipated operative position.

Upper Extremity Positioning

- Arm abduction should be limited to 90 degrees in supine patients; patients who are positioned prone may comfortably tolerate arm abduction greater than 90 degrees.
- Arms should be positioned to decrease pressure on the post-condylar groove of the humerus (ulnar groove). When arms are tucked at the side, a neutral forearm position is recommended. When arms are abducted on arm boards, either supination or a neutral forearm position is acceptable.

- Prolonged pressure on the radial nerve in the spiral groove of the humerus should be avoided.
- Extension of the elbow beyond a comfortable range may stretch the median nerve.

Lower Extremity Positioning

- Lithotomy positions that stretch the hamstring muscle group beyond a comfortable range may stretch the sciatic nerve.
- Prolonged pressure on the peroneal nerve at the fibular head should be avoided.
- Neither extension nor flexion of the hip increases the risk for femoral neuropathy.

Protective Padding

- Padded arm boards may decrease the risk for upper extremity neuropathy.
- The use of chest rolls in laterally positioned patients may decrease the risk for upper extremity neuropathies.
- Padding at the elbow and at the fibular head may decrease the risk for upper and lower extremity neuropathies, respectively.

Equipment

- Properly functioning automated blood pressure cuffs on the upper arms do not affect the risk for upper extremity neuropathies.
- Shoulder braces in steep head-down positions may increase the risk for brachial plexus neuropathies.

Postoperative Assessment

- A simple postoperative assessment of extremity nerve function may lead to early recognition of peripheral neuropathies.

Documentation

- Charting specific positioning actions during the care of patients may result in improvements of care by (1) helping practitioners focus attention on relevant aspects of patient positioning and (2) providing information that continuous improvement processes can use to effect refinements in patient care.

Modified from American Society of Anesthesiologists Task Force on Prevention of Perioperative Peripheral Neuropathies. Practice advisory for the prevention of perioperative peripheral neuropathies: a report by the American Society of Anesthesiologists Task Force on Prevention of Perioperative Peripheral Neuropathies. *Anesthesiology*. 2000;92(4):1168–1182.

The supine position, used in abdominal, pelvic, and penile procedures, is in general considered the safest patient position. However, several specific issues should be considered. **Excessive upper extremity abduction (>90 degrees) can lead to tension on the brachial plexus, causing upper extremity neuropathy.** The arm board should be padded to avoid excessive pressure on the ulnar groove and spiral groove of the humerus (radial nerve injury). In cases in which the arms are tucked at the patient's side, care must be taken to avoid excessive pressure on the hand and forearm. Moreover, peripheral intravenous catheter infiltration must be identified quickly because forearm compartment syndrome may develop.

One of the most frequent positions used in urology is the lithotomy position. Improper positioning can lead to transient and occasionally prolonged lower extremity neuropathy. In a retrospective evaluation of more than 190,000 cases from 1957 to 1991 involving the lithotomy position, persistent neuropathy was found in 0.03%; however, the same group in a prospective study of 991 patients reported an incidence of 1.5% (15 patients), with resolution of symptoms by 6 months in all but one patient (Warner et al., 1994, 2000). **The basic principle of positioning involves manipulation of both lower extremities *simultaneously* with flexion of the hips at 80 to 100 degrees with 30- to 45-degree abduction.** The legs should be padded to avoid excessive compression against the stirrup. Particular caution should be given to the patient's hands to avoid entrapment within the moving parts of the stirrups.

For most open and laparoscopic upper urothelial tract and renal procedures, the patient is placed in some degree of lateral decubitus position. Proper padding of the patient is important, with appropriate anterior and posterior support to maintain the decubitus position. The most frequent focus of compromise involves positioning of the arms and the potential for brachial plexus injury. The ipsilateral arm should be placed on the chest or an elevated arm rest or gel pad, or pillow (s) avoiding abduction of more than 90 degrees and excessive stretch on the shoulder. The contralateral arm should be placed on an arm board with ulnar padding. Furthermore, in patients in full flank position, an axillary roll should be placed just caudal to the axilla (not in the axilla) to avoid compression of the contralateral brachial plexus. Finally, after the patient has been positioned and before sterile draping, the operating table should be fully rotated to ensure that the patient is adequately secured in all positions.

Two patient positions used in specific urologic cases deserve attention: the prone position for percutaneous nephroscopy and the full Trendelenburg position for robotic-assisted laparoscopic procedures in the pelvis. In the prone position, special care should be taken to pad the torso, elbows, hips, and legs. The anesthesiologist should ensure that the endotracheal tube and all vascular accesses are properly secured. Coordination of the entire team is required during transfer from the supine position on the stretcher to the prone position on the operating room table. A stretcher should always be available immediately in case of airway compromise and the need for rapid transfer to the supine position. Regarding the full Trendelenburg position for minimally invasive pelvic procedures, the primary issues involve the physiologic changes in respiratory function, cardiovascular function, and increases in central venous and intracranial pressures. **Patient positioning should focus on properly padding and securing the patient to the operating table to prevent cephalad sliding. Although fixed shoulder braces will undoubtedly prevent patient movement, these braces should be avoided because of the risk for brachial plexus compression and resultant neuropathy.**

Antibiotic Prophylaxis

In 1999 the Centers for Disease Control and Prevention (CDC) issued its third report on the prevention of SSI, highlighting the importance of standardization of prophylactic treatment to prevent this universal surgical complication (Mangram et al., 1999). **The report indicated that SSIs account for approximately 40% of nosocomial infections in surgical patients and potentially prolong hospital stay by 7 to 10 days.** A study of national SSIs from the 2005 Healthcare Cost and Utilization Project National Inpatient Sample

(HCUP NIS) calculated an increase in hospital stay of 9.7 days and in per-patient cost of $20,892 (de Lissovoy et al., 2009). This translated nationally into an additional 1 million inpatient hospital days and additional health care cost of $1.6 billion. Bowater et al. published a systematic review of meta-analyses (level 1 evidence) and concluded that there was substantial evidence that antibiotic prophylaxis was an effective prevention for SSI over a wide variety of surgical procedures (Bowater et al., 2009). **Given both the ethical responsibility of the surgeon to decrease surgical morbidity and the recent policy shift by the Centers for Medicare and Medicaid Services to withhold reimbursement for hospital admissions secondary to specific SSI, it is mandatory for urologists to understand the principles behind and to practice SSI prevention.**

Along with antibiotic prophylaxis, proper hand washing and scrubbing and sterile preparation of the operative field have always been central to the prevention of SSI. For procedures involving the GI tract, mechanical and oral antibiotic bowel preparation had been standard practice until more recent literature, calling into question its usefulness (discussed later). Preoperative hair removal has not been associated with a decrease in SSI, but if performed, use of mechanical clippers or depilatory creams as opposed to razors is associated with a decreased risk for SSI (Wolf et al., 2008).

The risk for SSI and therefore the recommendation for antibiotic prophylaxis is composed of three factors: the patient's susceptibility to and ability to respond to localized and systemic infection, the procedural risk for infection, and the potential morbidity of infection. First, patient-related factors, listed in Box 8.3, increase risk by decreasing natural defense mechanisms, increasing the local bacterial concentration, and/or altering the spectrum of bacterial flora. Second, surgical procedure–specific factors can affect the route of entry, site of infection, and pathogen involved. This idea was first described in the landmark study from the National Research Council and later formalized by the CDC; specifically, surgical wounds are now classified by degree of contamination (i.e., the inoculum of potential pathogen) (Box 8.4; Hart et al., 1968). To predict the risk for SSI, several scoring systems have been developed incorporating patient-related factors with wound classification. Finally, the risk to the patient from SSI is an important consideration in determining the need for prophylaxis. For example, routine cystoscopy in the evaluation of microhematuria in an otherwise young, healthy patient may not warrant prophylaxis; however, the same procedure in an elderly, insulin-dependent diabetic (immunocompromised) does warrant prophylaxis given the high likelihood that a postprocedural urinary tract infection would result in a significant deterioration in the patient's overall health. Understanding the three factors together then allows the urologist to make a rational decision regarding the risks and benefits of antibiotic prophylaxis.

Box 8.3

Patient Factors That Increase the Risk for Infection

- Advanced age
- Anatomic anomalies
- Poor nutritional status
- Smoking
- Chronic corticosteroid use
- Immunodeficiency
- Chronic indwelling hardware
- Infected endogenous or exogenous material
- Distant coexistent infection
- Prolonged hospitalization

Data from Cruse PJ. Surgical wound infection. In: Wonsiewicz MJ. ed. Infectious disease. Philadelphia, PA: Saunders; 1992:758–764; Mangram AJ, Horan TC, Pearson ML, et al. Guideline for prevention of surgical site infection, 1999. Hospital Infection Control Practices Advisory Committee. *Infect Control Hosp Epidemiol*. 1999;20(4):250–278; quiz 279–280.

Box 8.4

Surgical Wound Classification

Clean

- Uninfected wound without inflammation or entry into the genital, urinary, or alimentary tract
- Primary wound closure, closed drainage

Clean Contaminated

- Uninfected wound with controlled entry into the genital, urinary, or alimentary tract
- Primary wound closure, closed drainage

Contaminated

- Uninfected wound with major break in sterile technique (gross spillage from gastrointestinal tract or nonpurulent inflammation)
- Open fresh accidental wounds

Dirty Infected

- Wound with preexisting clinical infection or perforated viscera
- Old traumatic wounds with devitalized tissue

Data from Garner JS. CDC guideline for prevention of surgical wound infections, 1985. Supersedes guideline for prevention of surgical wound infections published in 1982. (Originally published in 1995.) Revised. *Infect Control.* 1986;7(3):193–200; Simmons BP. Guideline for prevention of surgical wound infections. *Infect Control.* 1982;2:185–196.

Once the decision for antibiotic prophylaxis has been made, the keys to successful prevention are the proper choice of antibiotic for the particular procedure and proper timing and administration of the antibiotic. The first key to successful prevention is the proper choice of antibiotic for the procedure in question. As mentioned earlier, surgery-specific factors affect the type of pathogen, route of entry, and likelihood of systemic infection. For example, the choice of antibiotic is different for TURP (need coverage for common urinary tract pathogens) than for a cystectomy with planned sigmoid colon urinary diversion (need coverage for anaerobic bacteria). Another important consideration is the rate of antibiotic resistance in the community**. Although there is level 1 evidence for the use of fluoroquinolones as prophylaxis for urologic endoscopic procedures, the emerging *Escherichia coli* resistance in the community is changing practice patterns in many practices and high-resistance hospitals.** One resource that is particularly useful is the hospital antibiogram. These reports are published monthly at most major hospitals and quantify the susceptibility and resistance of common organisms to a wide variety of antibiotics. A summary of the recent American Urological Association (AUA) best practice statement on antibiotic prophylaxis is shown in Table 8.5. In 2012, the AUA issued an amendment to the best practice statement with regard to prostate biopsy, acknowledging the emerging resistance to fluoroquinolones and recommending cephalosporins and/or aminoglycosides in certain communities.

TABLE 8.5

American Urological Association Best Practice Statement on Recommended Antimicrobial Prophylaxis for Urologic Procedures

PROCEDURE	ORGANISM	PROPHYLAXIS INDICATED	ANTIMICROBIALS OF CHOICE	ALTER ANTIM
LOWER URINARY TRACT INSTRUMENTATION				
Removal of external urinary catheter	GU tract	If risk factors	Fluoroquinolone TMP-SMX	Ami ampi First- gene ceph Amo
Cystography, urodynamic study, or simple cystoscopy	GU tract	If risk factors	Fluoroquinolone TMP-SMX	Ami ampi First- gene ceph Amo
Cystoscopy with manipulation	GU tract	All	Fluoroquinolone TMP-SMX	Ami ampi First- gene ceph Amo
Prostate brachytherapy or cryotherapy	Skin	Uncertain	First-generation cephalosporin	Clindam
Transrectal prostate needle biopsy	Intestine	All	Fluoroquinolone Second- or third-generation cephalosporin	Aminogl metronid clindamy

UPPER URINARY TRACT INSTRUMENTATION				
Shock wave lithotripsy	GU tract	All	Fluoroquinolone TMP-SMX	Ami ampi First- gene ceph Amo
Percutaneous renal surgery	GU tract Skin	All	First- or second-generation cephalosporin Aminoglycoside + metronidazole or clindamycin	Amp Fluo
Ureteroscopy	GU tract	All	Fluoroquinolone TMP-SMX	Ami ampi First- gene ceph Amo
OPEN OR LAPAROSCOPIC SURGERY				
Vaginal surgery (including urethral sling procedures)	GU tract Skin Group B Streptococcus	All	First- or second-generation cephalosporin Aminoglycoside + metronidazole or clindamycin	Amp Fluo
Open or laparoscopic surgery without entering GU tract	Skin	If risk factors	First-generation cephalosporin	Clindam
Surgery involving entry into GU tract	GU tract Skin	All	First- or second-generation cephalosporin Aminoglycoside + metronidazole or clindamycin	Amp Fluo
Intestinal surgery	GU tract Skin Intestinal flora	All	Second- or third-generation cephalosporin Aminoglycoside + metronidazole	Amp Tica Pipe Fluo

			or clindamycin	
Implanted prosthesis	GU tract Skin	All	Aminoglycoside + first- or second-generation cephalosporin or vancomycin	Amp Tica Pipe

Modified from Wolf JS Jr, Bennett CJ, Dmochowski RR, et al.; Urologic Surgery Antimicrobial Prophylaxis Best Practice Policy Panel. Best practice policy statement on urologic surgery antimicrobial prophylaxis. *J Urol*. 2008;179(4):1379–1390.

Since the pivotal study by Classen et al., particular emphasis has been placed on the timing of prophylaxis to be given within 2 hours of incision (Classen et al., 1992). This emphasis was exemplified by the Joint Commission's Surgical Care Improvement Project (SCIP) guideline for administration of antibiotic prophylaxis 60 minutes before incision in a broader effort to decrease overall surgical complications by 25% by 2010. A multi-institutional trial involving more than 4400 patients at 29 institutions reported results of their analysis on the optimal timing of antibiotic prophylaxis (Steinberg et al., 2009). **The results suggested an improvement in prevention of SSI when antibiotics were administered within 30 minutes of incision as compared with 31 to 60 minutes (adjusted odds ratio [OR] 1.48, *P* = .06).** More importantly, this larger study confirmed the significantly increased risk for SSI when antibiotics were administered at the time of or after incision, with an adjusted OR of 2.20, *P* = .02. The duration of antibiotic prophylaxis is more controversial; however, **most recommendations advocate no more than 24 hours in a patient without an established infection.** Routine antibiotic use beyond 24 hours increases the risk for *C. difficile* colitis, increases the development of antibiotic resistance, and increases costs. Along with timing and duration, proper administration of antibiotics implies proper dosage. Antibiotic dose is dependent on the patient's body weight, renal function and hepatic function, and duration of procedure (re-administration is required if longer than 4 hours). A recent analysis of the Premier Perspectives Database encompassing urologic procedures performed between 2007 and 2012 revealed that compliance with AUA Best Practices increased with time, but overall rates remain less than 60% (Mossanen et al., 2015). **A practicing urologist must be familiar with best practice guidelines and hospital policies to avoid underuse, overuse, or misuse of antimicrobial prophylaxis.**

Venous Thromboembolic Prophylaxis

Venous thromboembolic complications are a major cause of potentially preventable morbidity and mortality among surgical patients in the United States. A recent study from the Center for Quality Improvement and Patient Safety and the Agency for Healthcare Research and Quality found postoperative VTE to be the second most common cause of excess length of stay, charges, and mortality among surgical patients discharged from acute care hospitals (Zhan and Miller, 2003). Urology patients in particular have an increased incidence of VTE, estimated to be 10% to 40% in patients without any prophylaxis (Geerts et al., 2008). Although these estimates are based on historical studies conducted before the routine use of mechanical prophylaxis and the recognition of the benefits of early ambulation, the increased risk persists, with more recent studies reporting incidences of 1% to 5%. Urologic patients followed prospectively in the European @RISTOS study developed VTE in 1.9% undergoing open surgery despite a high rate of prophylaxis (Scarpa et al., 2007). For patients in the United Kingdom undergoing urologic procedures, Dyer et al. reported an overall incidence of 0.66% including a 2.8% incidence among patients undergoing radical cystectomy (Dyer et al., 2013). Overall, VTE is the most important cause of nonsurgical mortality among urology patients (Forrest et al., 2009).

Although the use of perioperative mechanical prophylaxis (pneumatic compression stockings or sequential compressive device) is fairly universal, pharmacologic prophylaxis is administered only after weighing the risk for VTE versus the risk for perioperative bleeding complications (Table 8.6). Leonardi et al. reviewed and analyzed 33 RCTs to assess the incidence of bleeding complications in general surgery patients receiving pharmacologic prophylaxis (Leonardi et al., 2006). **Although there was a significantly higher rate of minor complications (injection site bruising and wound hematoma), there was no significant difference in major complications (e.g., GI tract bleeding [0.2%] or retroperitoneal bleeding [<0.1%]).** Although these results are applicable in general to urology patients, certain urologic procedures, such as TURP and partial nephrectomy, have a specifically higher rate of bleeding complications. Regarding an individual's risk for VTE, both surgery-related risk factors and patient-related risk factors must be considered. Surgical factors specific to urologic surgery to be weighed include general versus neuraxial anesthesia, supine versus dorsal lithotomy positioning, abdominal versus pelvic surgery with or without lymphadenectomy, and open versus laparoscopic approach. Patient-related risk factors are listed in Box 8.5, with increasing age, malignancy, history of cancer therapy, and others being fairly common among urology patients. In fact, both the @RISTOS study and a recent report on minimally invasive radical prostatectomy confirmed several of these factors as being associated with increased risk for VTE in urologic patients (Scarpa et al., 2007; Secin et al., 2008). In 2008, the ACCP issued guidelines on the prevention of VTE with a strong recommendation that hospitals develop a formal, active strategy to address VTE prevention. **Although prior recommendations from the ACCP advocated individualized risk assessment models to guide therapy, the current recommendations advocate implementation of group-specific thromboprophylaxis routinely for all patients who belong to each of the major surgical groups (e.g., urologic surgery)** (Geerts et al., 2008). The AUA has published a best practice statement on the use of VTE prophylaxis in urologic patients (Forrest et al., 2009). These recommendations combine an individualized risk assessment model with each type of urologic surgery. For example, a high-risk patient (multiple patient risk factors) undergoing low-risk surgery may require pharmacologic prophylaxis, as might a low-risk patient undergoing high-risk surgery. The recommendations are summarized in Table 8.7.

TABLE 8.6

Mechanical and Pharmacologic Venous Thromboembolism Prophylaxis

PROPHYLAXIS	DOSE	ADVANTAGES	DISADVANTAGES
Pneumatic compression stockings	N/A	Can be used in patients with high bleeding risk Easily standardized for all patients Studied in multiple patient groups	No standards for size, pressure Individual models not specifically studied Less effective than pharmacologic prophylaxis in high-risk groups
Low–molecular-weight heparin	40 mg SC once daily	Once-daily administration Less risk for heparin-induced thrombocytopenia No blood monitoring necessary	Not reversible High cost Relative contraindication in patients with renal insufficiency

Low-dose unfractionated heparin	5000 units SC q8h	Reversible Can be used safely in patients with renal insufficiency Relatively inexpensive	Needs readministration q8-12h Heparin-induced thrombocytopenia

Box 8.5

Patient-Related Factors Increasing Risk for Venous Thromboembolism

- Surgery
- Trauma (major trauma or lower extremity injury)
- Immobility, lower extremity paresis
- Cancer (active or occult)
- Cancer therapy (hormonal, chemotherapy, angiogenesis inhibitors, radiotherapy)
- Venous compression (tumor, hematoma, arterial abnormality)
- Previous venous thromboembolism
- Increasing age
- Pregnancy and the postpartum period
- Estrogen-containing oral contraceptives or hormone replacement therapy
- Selective estrogen receptor modulators
- Erythropoiesis-stimulating agents
- Acute medical illness
- Inflammatory bowel disease
- Nephrotic syndrome
- Myeloproliferative disorders
- Paroxysmal nocturnal hemoglobinuria
- Obesity
- Central venous catheterization
- Inherited or acquired thrombophilia

TABLE 8.7

Patient Risk Assessment Model and American Urological Association Best Practice Recommendations

PATIENT RISK STRATIFICATION	
Low risk	Minor surgery in patients younger than 40 yr with no additional risk factors
Moderate risk	Minor surgery in patients with additional risk factors Surgery in patients 40–60 yr with no additional risk factors
High risk	Surgery in patients older than 60 yr Surgery in patients 40–60 yr with additional risk factors (see Box 8.4)
Highest risk	Surgery in patients with multiple risk factors (e.g., age older than 40 yr, cancer, prior venous thromboembolism)
LEVEL OF RISK	RECOMMENDATIONS
Low risk	No prophylaxis other than early ambulation
Moderate risk	Heparin 5000 units q12h SC starting after surgery or Enoxaparin 40 mg (for CrCl <30 mL/min, use 30 mg) SC daily or Pneumatic compression device if risk for bleeding is high
High risk	Heparin 5000 units q12h SC starting after surgery or Enoxaparin 40 mg (for CrCl <30 mL/min, use 30 mg) SC daily or Pneumatic compression device if risk for bleeding is high
Highest risk	Enoxaparin 40 mg (for CrCl <30 mL/min, use 30 mg) SC daily and adjuvant pneumatic compression device or Heparin 5000 units q8h SC starting after surgery and adjuvant pneumatic compression device

CrCl, Creatinine clearance; *yr,* year.

Anesthetic Considerations

The basic tenet of anesthesia is to deliver hypnosis, amnesia, and analgesia while maintaining satisfactory operating conditions. An understanding of the basic pharmacologic principles, anesthetic equipment and monitoring, and patient analgesia is important to any surgeon including the urologist for successful operative outcomes and avoidance of surgical complications. Although urologists are performing increasingly more procedures in the office, the bulk of urologic surgery occurs in the operating room under monitored anesthesia care, regional anesthesia, or general anesthesia. Current practice in operative anesthesia employs a combination of inhalational agents and intravenous medications along with analgesics (for pain control) and benzodiazepines (for anxiolysis and amnesia). Of course, improved presurgical evaluation, pharmacologic drugs, and perioperative monitoring have dramatically decreased the risks associated with anesthesia. A recent study of New York hospital-based and freestanding ambulatory surgical centers reported the risk for all-cause mortality to be 1 in 49,012 and the rate of immediate admission to an inpatient facility to be 0.6% (Fleisher et al., 2007b).

Selection of Mode of Anesthesia

An important role of the urologist in the anesthetic evaluation is to determine what mode of anesthesia is best for the particular patient and surgical procedure. The choice depends on patient-related factors including comorbidities, airway, and patient preference and procedural factors including complexity, duration, anatomic location, and expected fluid and blood loss. A basic understanding of each method of anesthesia and the pharmacologic principles will aid the urologist in making recommendations to the anesthesiologist.

Monitored Anesthesia Care

Although *monitored anesthesia care* is defined as conscious sedation under the care of an anesthesiologist in a monitored situation, it encompasses a wide range of levels of anesthesia from minimal sedation to brief intervals of unconscious general anesthesia. Most commonly, anesthesiologists combine intravenous opioid analgesics and benzodiazepines to maintain a sufficient level of patient comfort and anxiolysis. Monitored anesthesia care is widely used in urology in the ambulatory setting and is suitable for short-duration endoscopic procedures, transrectal ultrasound-based procedures, and, when combined with a local anesthetic, superficial procedures of the external genitalia. Conscious sedation can be administered in the office setting, but only with proper monitoring of the patient during and after the procedure. **The Joint Commission has strict guidelines to ensure that the patients receive the same level of monitoring as if under the care of an anesthesiologist including a requirement for a trained monitoring assistant, immediate access to airway and resuscitation equipment, and specific preprocedure and postprocedure evaluations.**

Regional Anesthesia

Regional anesthesia incorporates different levels of anesthesia directed toward the surgical site, including local anesthesia, spinal anesthesia, and epidural anesthesia. The use of local anesthetics is typically combined with monitored anesthesia care for superficial procedures in an isolated anatomic location. The keys to proper local anesthetic administration are avoidance of intravascular injection and knowledge of pharmacology. The two most commonly used drugs are lidocaine and bupivacaine, with the primary differences being the onset and duration of action. Infiltration of local anesthetics before surgical incision decreases nociceptor sensitization and conduction and results in decreased postoperative pain and analgesic requirements.

Spinal and epidural anesthesia involves injection of anesthetic (most commonly lidocaine or bupivacaine) into the subarachnoid space or epidural space with direct effect on the spinal cord, resulting in sensory, motor, and sympathetic blockade. In urologic procedures, epidural anesthesia is most useful for postoperative pain management for major abdominal procedures, thereby avoiding the adverse effects of high doses of intravenous opioids (i.e., respiratory depression, GI dysfunction). Spinal anesthesia is suitable for most urologic endoscopic procedures and lower abdominal surgical procedures and is limited only by the duration of anesthesia required. Spinal anesthesia avoids the cardiopulmonary effects and complications of general anesthesia. Several factors affect the spinal level and efficacy of administration. In general, larger volume and increased doses result in longer duration and increased cephalad migration. The addition of low-dose opioids and/or vasoconstrictors prolongs the duration of analgesia while reducing the dose of anesthetic. The anesthetic-related adverse effect is hypotension as a result of sympathetic blockade and occurs in 10% to 40% of patients (Di Cianni et al., 2008). **The primary technique-related complication is post–dural puncture headache (results from cerebrospinal fluid leak) with an incidence of less than 2% with currently**

used 29-gauge pencil-tipped needles (Turnbull and Shepherd, 2003). **Overall, spinal anesthesia has become safe, with the incidence of serious neurologic deficits being 0.05%.**

General Anesthesia

Inhalational General Anesthesia.

Inhalational drug development has emphasized inhalational agents that facilitate rapid induction and emergence and are nontoxic. **Two of the most important characteristics of inhalational anesthetics are the blood/gas solubility coefficient (B/G) and the minimum alveolar concentration (MAC). The B/G refers to the serum uptake of the inhaled agent, and the MAC is a measure of the potency of a volatile anesthetic (i.e., the serum level required to prevent movement in response to a skin incision in 50% of patients).** The various inhalational agents differ not only in the B/G and MAC but also in their cardiopulmonary effects. Obviously, a basic understanding of these properties is important for the urologic surgeon, especially during instances of surgical complication.

Nitrous oxide (NO) is one of the most commonly used agents because of its propensity for rapid induction and emergence; however, because of its low potency, it is often combined with other agents. **Because of NO's high B/G and tendency to increase the volume and pressure of closed spaces, its use is contraindicated in certain clinical situations such as small bowel obstruction and pneumothorax. During laparoscopic abdominal procedures, surgeons often prefer to avoid the use of NO because of resultant bowel distention and subsequent interference in the operative field.** Although this effect is debated in the surgical literature, El-Galley et al. reported significantly increased bowel distention and surgical interference with NO use in patients undergoing laparoscopic donor nephrectomy (El-Galley et al., 2007).

Once introduced in the 1950s, halothane rapidly became one of the most commonly used anesthetic agents because of its high potency. **However, halothane has several important risks that have since limited its use. It has significant cardiac effects and can precipitate failure in patients with left ventricular dysfunction. Furthermore, it sensitizes the myocardium to the effects of catecholamines (relevant for local anesthetics injected into the surgical site).** Finally, there is a 1 in 35,000 incidence of fulminant hepatitis, which can be lethal as a result of overaccumulation of toxic metabolites. More recent advancements in inhalational agents have focused on reduction in toxicity while maintaining the potency and rapidity of halothane. **Three of the most commonly used current agents are isoflurane, sevoflurane, and desflurane**. Isoflurane, less expensive than the other agents because of the availability of generic equivalents, is widely used as a result of its low cardiac depression, lower myocardial sensitization to catecholamines, and minimal metabolism. The primary unique toxicity is a variable response to tachycardia, which can lead to significantly increased myocardial oxygen consumption. Unlike isoflurane, which has a putrid odor, sevoflurane is often used for inhalation induction (odorless) because of its rapid induction and emergence, decreased incidence of postoperative nausea (important in outpatient surgery), and minimal cardiac toxicity. It is, in general, the preferred agent for difficult airways requiring mask induction and in patients with severe bronchospastic disease. Desflurane, like isoflurane, has a pungent odor and is not used for inhalational induction. Its primary advantage over isoflurane is a more rapid recovery in patients requiring anesthesia for more than 3 hours.

Intravenous General Anesthesia.

Intravenous anesthesia consists of a combination of induction agent, opioid, and neuromuscular relaxant. Anesthesiologists often prefer intravenous induction with a combination of inhalational and intravenous agents for maintenance of anesthesia. Intravenous induction offers several advantages in that it is rapid, minimizes patient discomfort, and is preferred by children and most adults. Thiopental, the oldest and least expensive agent, is a suitable choice for uncomplicated situations but is limited in more complex cases because of its significant vasodilation, cardiac depression, and risk for bronchospasm, especially in patients with reactive airway disease. Ketamine is a preferred choice for procedures that are brief and superficial because of its profound amnesia and somatic analgesia. It is associated with increased arteriolar and bronchomotor tone and is advantageous during induction for hypovolemic and asthmatic patients. **Propofol is among the most commonly used anesthetic agents, especially in outpatient surgery. It has a rapid onset, produces excellent bronchodilation in patients with reactive airway disease, and, perhaps most important, is associated with smooth, nausea-free emergence from anesthesia.** Its primary adverse effect is significant blood pressure reduction. Midazolam, never used as a single agent, produces profound amnesia and anxiolysis while having a rapid onset and short duration and producing minimal cardiac side effects. Although these agents induce unconsciousness and amnesia, opioids have become an integral component to all forms of anesthesia. Opioids result in significant analgesia without an increase in cardiac side effects. Opioids also results in decreased requirements of other agents when used in combination, thus reducing the overall cardiopulmonary side effects of anesthesia. Opioids themselves are differentiated in their potency, onset of action, duration of action, and metabolism and excretion. **Fentanyl (synthetic opioid) is probably the most widely used because of its potency (100 to 150 times that of morphine), rapid onset, and short duration of action.** Newer synthetics are geared toward shorter duration and more rapid metabolism.

For major operative cases, complete neuromuscular relaxation is required for sufficient exposure and successful outcome. Although full relaxation can be achieved with intravenous and inhalational agents, the dose required is extremely high. The use of intravenous neuromuscular blockers allows for neuromuscular relaxation and minimization of inhalational and intravenous drugs. **There are two types of neuromuscular blockers: depolarizing drugs, which depolarize the plasma membrane of skeletal muscle fibers, making the fibers resistant to further stimulation by acetylcholine, and nondepolarizing drugs, which block the binding of acetylcholine to cholinergic receptors on the presynaptic and postsynaptic membrane.** Succinylcholine, the only depolarizing drug on the market, is chosen for its rapid onset (used in rapid induction sequences), relatively short duration (around 5 minutes), and rapid metabolism. Its use is limited because of the risk for malignant hyperthermia (when used in combination with volatile inhalational agents), hyperkalemia, and bradycardia in children. When succinylcholine is contraindicated, nondepolarizing agents are used. Several nondepolarizing drugs are available and differ in routes of metabolism and adverse effects. Furthermore, multiple medications including desflurane can alter the metabolism of these drugs and potentiate their actions. The most important consideration in the use of neuromuscular blockers is the assessment of adequate return of neuromuscular function after withdrawal of the drug.

The most common complication of neuromuscular-blocking drugs is inadequate reversal resulting in respiratory failure and reintubation. Numerous reports in the literature correlate residual neuromuscular blockade with increased postoperative pulmonary complications in the postanesthesia care unit (PACU) and in the postoperative period. **The concept of train-of-four fade ratio (TOF) was developed to devise an objective measure of adequate neuromuscular**

function. This concept refers to the magnitude of the fourth of four twitches in response to maximal stimuli to the ulnar nerve delivered at 0.5-second intervals. Historically, a TOF of 0.7 (meaning that the fourth twitch was 70% the magnitude of the first twitch) correlated with adequate return of neuromuscular function; however, more recent standards have raised the threshold to 0.9 as an indicator of complete return of neuromuscular function (Kopman et al., 1997). Currently, anesthesiologists use several clinical assessments including head lift, tongue depressor test, and hand grip to estimate a TOF of 0.9. A recent study revealed that with use of clinical assessments alone, 16% and 45% of patients 2 hours after a single intubating dose of neuromuscular blocker had a TOF of less than 0.7 and less than 0.9, respectively, in the PACU (Debaene et al., 2003). As such, quantitative TOF measurement (acceleromyography) should be combined with clinical assessments before extubation in the operating room.

Skin Preparation

Sterile skin preparation is fundamental in the prevention of SSI for any procedure. Currently the most commonly used skin antiseptics are alcohol, povidone-iodine, or chlorhexidine based. Whichever antiseptic is chosen, the solution should be applied in concentric circles from the center of the surgical site and allowed to dry before incision. **The Cochrane Wound Study group recently published their updated analysis on various preoperative skin preparations. The authors found some evidence that preoperative skin preparation with 0.5% chlorhexidine in methylated spirits was associated with lower rates of SSI after clean surgery than alcohol-based povidone iodine paint but were unable to report conclusive evidence of superior efficacy of one particular skin preparation** (Dumville et al., 2013). Furthermore, although the CDC clearly recommends preoperative showering or bathing to reduce SSI, **there is no evidence that bathing with an antiseptic solution reduces the rate of infection** (Webster and Osborne, 2015). Regarding hair removal, the CDC recommends that if hair removal is performed, it should be performed immediately before the surgical procedure and performed with clippers (rather than shaving) to avoid breakage in the continuity of the integument and the resulting bacterial colonization (Mangram et al., 1999).

Transfusion Considerations

Given the vascular nature of urologic organs, the urologist often confronts the issue of blood loss in the perioperative period. Therefore, it is imperative that the urologist understand the implications and risks associated with blood product transfusion. Additionally, the urologist should be familiar with transfusion alternatives for patients who will not accept blood transfusions, such as Jehovah's Witnesses.

Before the acquired immunodeficiency syndrome (AIDS) epidemic, blood transfusion was liberally administered, often for any patient with a hematocrit less than 30%. However, fear and concern about the infectious risk led to the convening of a National Institutes of Health (NIH) panel to develop consensus recommendations for the indication of blood product transfusion (National Institutes of Health, 1988). The principles in these guidelines are reflected by the ASA practice guidelines issued in 2006 (American Society of Anesthesiologists Task Force on Perioperative Blood Transfusion and Adjuvant Therapies, 2006). **To summarize, the guidelines indicate that transfusion is rarely indicated with hematocrit greater than 30% and often indicated for a hematocrit less than 21%. For levels between 21% and 30%, clinical factors such as risk for complications from inadequate oxygenation should guide the need for transfusion, balancing the risks and benefits.** In general, patients with relatively minor comorbidities can tolerate hematocrit of greater than 21%. Patients with moderate to severe comorbidity (e.g., significant pulmonary compromise, coronary artery disease, or vascular insufficiency, or with signs or symptoms of hypovolemic, hemorrhagic shock) may not tolerate a hematocrit less than 30%. Ultimately, until technology is available to directly measure inadequate oxygen-carrying capacity, the urologist should individualize each patient's management based on the clinical situation.

A major advancement in blood banking and product transfusion has been the development of component therapy allowing for administration of specific fractions of whole blood. Packed red blood cells (PRBCs) are equivalent to whole blood minus the plasma component. Whereas the hematocrit in whole blood is 40%, it is 70% in PRBC units. These units are reconstituted and administered with crystalloid. Given the lack of the remaining components, in instances of massive PRBC transfusions and associated bleeding, platelets and occasionally fresh frozen plasma (FFP) are given to avoid dilutional coagulopathy. Platelet transfusion is rarely given empirically except in patients with significant thrombocytopenia ($<50,000/mm^3$) and a planned surgical procedure or with moderate thrombocytopenia ($50,000$ to $100,000/mm^3$) and either a high-risk procedure or evidence of platelet dysfunction. Similarly, empirical transfusion with FFP for massive transfusion is not standard practice. **The current indications for FFP transfusion are immediate reversal of warfarin-induced coagulopathy, replacement in patients with specific clotting factor deficiencies, and evidence of bleeding and INR greater than 1.5. According to ASA guidelines, in patients with massive transfusion and no INR readily available, FFP should be given after replacement of 1 blood volume.**

There are well-documented risks associated with blood transfusion, and these risks should always be discussed with the patient before administration. Hemolytic transfusion reactions occur as a result of incompatibility between donor and recipient (either ABO or non-ABO incompatibility). Transfusion reactions occur relatively frequently and, if identified early, can be treated with rare catastrophic events. The early signs and symptoms include fever, chills, chest pain, hypotension, and bleeding diathesis occurring during or immediately after transfusion. Reactions may also occur in a delayed fashion, characterized by significant intravascular hemolysis secondary to recipient antibodies. The treatment of transfusion reaction is centered on fluid resuscitation, cessation of the transfusion, and alkalinization of the urine to prevent renal failure. **The most common cause of transfusion-related fatality is transfusion-related acute lung injury (TRALI). This entity accounted for 55% of transfusion mortality from 2005 to 2007. The injury is characterized by noncardiogenic pulmonary edema and manifests 1 to 2 hours after transfusion.** Although no specific treatment other than supportive measures is indicated, most patients recover without significant sequelae.

Finally, one of the most feared complications (at least in the public eye) is the transmission of bacterial or viral infection. Although the risk for hepatitis virus and human immunodeficiency virus (HIV) transmission was unacceptably high in the 1970s and 1980s, the initiation of more stringent screening procedures for high-risk populations and the development of nucleic acid amplification technology (polymerase chain reaction [PCR] and transcription-mediated amplification) have resulted in dramatically reduced risk and incidence of viral transmission. **Currently, the risk for HIV and hepatitis C transmission is approximately 1 in 2 million cases, whereas the risk for hepatitis B transmission is 1 in 200,000.** The highest risk for infectivity occurs with platelet transfusion, in which bacterial contamination develops at a rate of 1 in 5000 units (Eder et al., 2007).

Given the proximity of major vascular structures to several genitourinary organs, occasionally the urologist is faced with a clinical situation in which a large-volume blood loss occurs, although very high–blood loss procedures in urology are uncommon. Traditionally, component transfusion would not begin until more than 6 units of PRBCs had been given to the patient. More recently, evidence from the trauma literature supports the use of an increased ratio of platelets to FFP to red blood cells (RBCs)—that is, massive transfusion protocol. The protocol is triggered in the anticipation of greater than 10 units of PRBCs per 24 hours and mobilizes blood bank and hospital resources to provide an adequate supply of RBCs and component transfusion. A study from Ball et al. demonstrated improved abdominal wall closure rates among patients with high-grade liver injuries when a massive transfusion protocol was used (Ball et al., 2013).

Several management strategies and transfusion alternatives are available for the management of patients with religious or other obligations not to accept blood transfusion. Contrary to popular beliefs, Jehovah's Witnesses’ refusal of blood transfusion does not indicate or translate to refusal of medical care. Importantly, they have respect for life and seek the best (bloodless) medical and surgical care available. Although *all* will not accept the four major blood components (RBCs, white blood cells, platelets, and plasma), some may accept minor blood fractions such as albumin, immunoglobulins, and clotting factors. A detailed discussion should be held with the patient, in conjunction with the anesthesiologist, to determine what is acceptable and what is not before initiating treatment. In the surgical patient, acceptable strategies include the use of electrocautery, cell salvage, intraoperative hemodilution, high-dose erythropoietin, and iron. Major surgical procedures have been performed with success without the use of blood transfusion, and some studies indicate that patients managed without blood had better outcome compared with those who received blood transfusion. Although there is currently no substitute for blood transfusion, several hemoglobin-based blood substitutes have been evaluated in various trials, but translation into routine clinical practice has been hindered by side effects or complications resulting from their use (Natanson et al., 2008).

Pain Management

Equally important to intraoperative anesthetic considerations, proper pain management after surgery is crucial to minimizing postoperative complications and delayed recovery. **Untreated acute pain not only is unacceptable for the patient, but also may increase the risk for complications by causing increased physiologic stress in the recovery period.** The neural process, referred to as *nociception,* involves signal transduction from noxious stimuli via sensory afferent nerves to the spinal cord and cerebral cortex, resulting in the perception of pain. Analgesia aims to block the pain sensation along various points of this signal transduction pathway.

Opioids are perhaps the most commonly used analgesic medications in the immediate postoperative period. These drugs primarily act in the central nervous system (CNS) at both the dorsal root ganglion and the cerebral cortex to modulate the perception of pain. Administration can be oral, intravenous, neuraxial, or transdermal. In general, the choice of route of administration is dependent on the patient's severity of pain and ability to take oral medications. Although typically very effective for providing analgesia, opioids can cause decreased GI activity resulting in ileus, respiratory depression, sedation, and mental confusion. Weaker (less potent) opioids such as hydrocodone and codeine may minimize these adverse effects but are often combined with acetaminophen and should be used with caution in patients with hepatic insufficiency. Additionally, opioid (mis)use has resulted in addiction and opioids epidemics in the United States (Jalal et al., 2018).

Physicians have a tremendous role to play in curbing the opioid crisis currently plaguing the United States (Waljee et al., 2017). In an effort to improve pain control and thus quality of care, advanced practice providers and surgeons often prescribe large amounts of narcotics, the majority of which are not used by the patients, and this contributes to dispersion of opioids into the community, misuse, abuse, and addiction (Lee et al., 2017; Theisen et al., 2018a, 2018b; Fujii et al., 2018; Cron et al., 2018). To underscore the significance of opioid overprescription, new persistent opioid use in patients undergoing minor and major surgeries has been reported to be up to 5.9% and 6.5%, respectively (Brummett et al., 2017). Thus, there are ongoing efforts to evaluate the judicious use of narcotic pain medicines in patients undergoing urologic surgery. For kidney stone management, for example, a recent analysis of 22,609 patients demonstrated a wide variation in opioid-prescribing patterns (Leapman et al., 2018). In a retrospective analysis of 104 patients undergoing ureteroscopy, 10% (5/52) of patients managed initially without narcotics and 17% (9/52) of patients managed initially with narcotics but sought additional medical care because of inadequate pain control, suggesting that patients undergoing ureteroscopy can be safely managed without narcotic pain pills (Large et al., 2018). Ongoing studies at various institutions will provide insight into the judicious use of narcotic analgesia after urologic surgeries.

Nonsteroidal anti-inflammatory drugs (NSAIDs) are being employed in the postoperative setting more frequently now to avoid the unwanted effects of opioids. These medications act by inhibition of cyclooxygenase enzyme activity, resulting in decreased prostaglandin production. Prostaglandins are the primary mediators of nociceptor activation at the tissue level. **Multiple studies have demonstrated that the appropriate use of NSAIDs can result in decreased use of opioid analgesics and decreased nausea and vomiting after anesthesia** (Rawlinson et al., 2012). In a randomized study of patients undergoing laparoscopic colon surgery, the use of intravenous ketorolac was associated with improved pain scores and reduced postoperative ileus (Schlachta et al., 2007). NSAIDs are usually very well tolerated but should be avoided in patients with renal insufficiency and used with caution in patients with a history of esophageal reflux or peptic ulcer disease.

For major abdominal surgery in which prolonged opioid use is expected, neuraxial analgesia (i.e., epidural) can provide significant patient benefits. Epidural analgesia is administered and monitored by the anesthesia or pain management team. Both opioids and local anesthetic medications are infused in the epidural space via catheter and are given as a continuous infusion and/or patient-controlled infusion. Epidural analgesia has the advantage of improved pain control while minimizing the CNS and GI adverse effects of intravenous opioid medications. Block et al. performed a meta-analysis of randomized trials to review the efficacy and concluded that epidural analgesia, regardless of agent or location of catheter placement, provided better pain control than parenteral opioids (Block et al., 2003). **In fact, a recent review of RCTs found that in patients undergoing general anesthesia, the use of concomitant epidural analgesia resulted in decreased perioperative mortality and improved comorbidity end points across multiple organ systems** (Pöpping et al., 2014).

Key Points

- Proper preoperative evaluation of the patient will prevent unanticipated cancellations and decrease the risk for postoperative complications.
- The indications for preoperative cardiac testing depend on three groups of

factors: the functional capacity of the patient, cardiac risk factors, and surgery-specific risk factors.

- SSIs are one of the leading causes of perioperative complications and increased hospital stay. Antibiotic prophylaxis is indicated in virtually all surgical procedures.
- VTE is a common complication of urologic procedures, and the AUA recommends either mechanical or pharmacologic prophylaxis (or both for patients at highest risk) for all urologic procedures.
- Proper understanding of the pharmacologic principles of anesthesia will allow the urologist to actively participate in the decision-making process of choosing which mode of anesthesia will be appropriate for a particular patient and procedure.
- Current guidelines advocate blood product transfusion for a hematocrit less than 21% in most patients unless there are specific cardiopulmonary risk factors.
- Perioperative hypothermia of even 1°C to 2°C is associated with increased estimated blood loss and increased risk for SSI.

Principles of Urologic Surgery

Incisions and Access

David Mikhail MD, FRCSC, Simon J. Hall MD

In the era of expanding experience, training, and indications for surgical robotics and laparoscopy, urologists are experiencing less exposure to traditional surgical techniques. Open incisions remain unpopular when there are minimally invasive alternatives and are associated with higher rates of unscheduled clinical encounters (phone calls, office visits) related to patient anxiety compared with endoscopic procedures (Arpey et al., 2018). However, there remain indications for open surgery based on patient driven characteristics, such as prior abdominal surgeries, use of prior abdominal mesh or size, and complexity of pathology (e.g., renal mass with a caval thrombus). Alternatively, and perhaps most importantly, the skill, experience, and comfort level of the individual surgeon and team may dictate an open versus minimally invasive procedure in more challenging cases. Furthermore, larger specimens such as polycystic kidneys, donor kidneys, or retroperitoneal sarcomas need to be extracted following a minimally invasive approach via an incision. Therefore, all operative urologists need to have a basic understanding of the various types of open incisions.

Abdominal Incisions

Midline Incision

Midline incisions are a commonly used abdominal incision. Through the midline, the extraperitoneal, peritoneal, and retroperitoneal spaces can be accessed.

The lower midline incision, also known as *infraumbilical*, provides access to the pelvic organs via the extraperitoneal, retropubic space (Space of Retzius) and intraperitoneal access when desired. There are multiple indications including radical retropubic prostatectomy, simple prostatectomy, pelvic lymph node dissection, radical cystectomy, partial cystectomy, diverticulectomy, enteric cystoplasty, and urinary diversions. This is also a common incision for extraction of specimens such as kidneys after laparoscopic surgery (Lee et al., 2017).

An upper midline incision can be utilized to access retroperitoneal structures bilaterally including the adrenal glands, kidneys, ureters, retroperitoneal lymph nodes, and great vessels. Procedures include retroperitoneal lymph node dissections, bilateral simple nephrectomies, and resection of retroperitoneal masses.

Various lengths are used depending on the procedure; as small as 2 to 3 cm for a suprapubic cystolithotomy. Either of the midline incisions can be extended (inferiorly or superiorly) past the umbilicus to allow improved exposure and access to abdominal and retroperitoneal organs as required. Procedures that could be done through a complete midline incision include retroperitoneal lymph node dissection, bilateral nephrectomy for polycystic kidneys, large retroperitoneal mass resection, nephroureterectomy or reconstruction requiring a significant amount of bowel for reconstruction (Indiana Pouch). This is also the approach in trauma nephrectomies (Carroll et al., 1989).

One should identify by palpation the linea alba, the aponeuroses of the abdominal wall muscles in the midline, and incise along it to avoid cutting through the rectus abdominus muscle. This becomes more challenging in patients who are obese, have had multiple abdominal surgeries, or have abdominal wall hernias. Avoiding the musculature decreases the risk for bleeding from the incision as it will avoid the vessels that run deep to and perforate the muscles (Fig. 9.1AB). With the lower midline incision, the extraperitoneal space is accessed by opening the posterior fascia as low as possible near the pubic bone to enter and then bluntly expand into this space. Alternatively, entrance into the peritoneal space can be made by opening the posterior fascia followed by the peritoneum.

FIG. 9.1 Cross-sectional and anterior abdominal wall anatomy. (A and B) Cross-sectional and anterior abdominal wall anatomy shown here is important to recognize when making abdominal incisions. Every attempt

should be made to avoid important vessels and nerves and to avoid direct incisions into the musculature when possible. (From Smith JA Jr, Howards SS, Preminger GM, Dmochowski RR. *Hinman's atlas of urologic surgery,* 4th ed. Philadelphia, PA: Elsevier, 2018; Figs. 3.1 and 8.1.)

Midline incisions are usually closed in one layer, keeping in mind that these will have more tension across the incision than those that conform to Langer's lines. Closure of fascial layers can be done in a running or interrupted figure-of-eight fashion with strong 2-0 synthetic monofilament absorbable sutures, such as Polydioxanone or braided Polyglycolide. Careful surgical technique is critical to avoid injury to abdominal structures and to ensure strength of the wound. Sutures should be 1 cm from midline and 1 cm apart (Figs. 9.2 and 9.3). There appears to be no evidence that one method is superior in terms of failure or subsequent incisional hernias (Patel et al., 2017), although one should avoid continuous closure technique if using any rapidly absorbable suture because this has been linked to higher hernia rates (Van ’t et al., 2002).

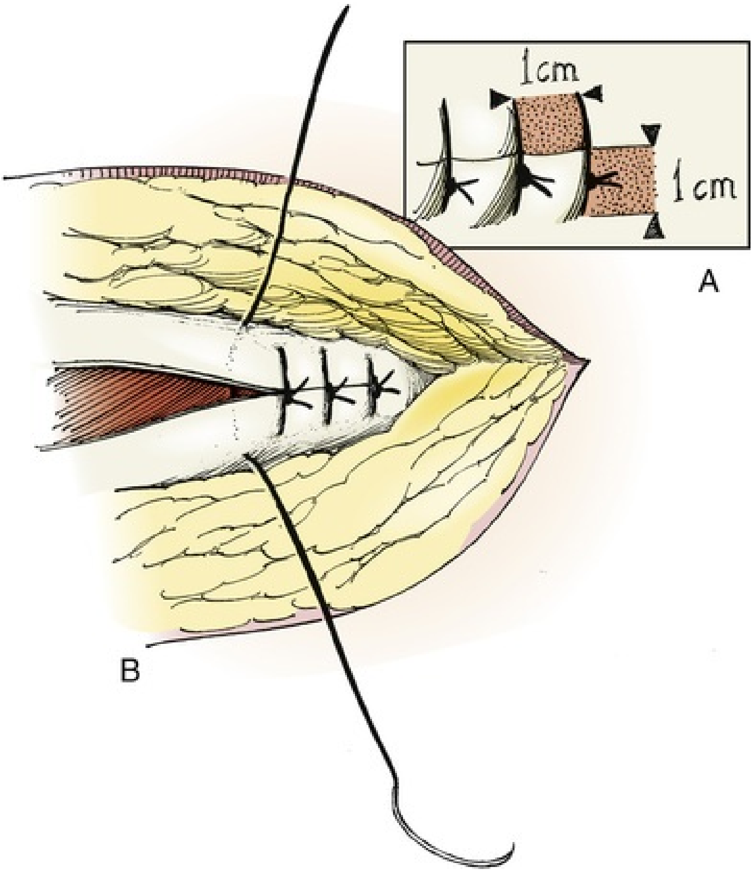

FIG. 9.2 Fascial closure technique. (A and B) Strong fascial closure is important in abdominal incisions. 2-0 non-absorbable sutures are usually

used and should be placed 1 cm from edge and 1 cm apart, as shown here. This can be done in an interrupted fashion (shown here) or running fashion. (From Smith JA Jr, Howards SS, Preminger GM, Dmochowski RR. *Hinman's atlas of urologic surgery,* 4th ed. Philadelphia, PA: Elsevier, 2018; Fig. 2.5AB.)

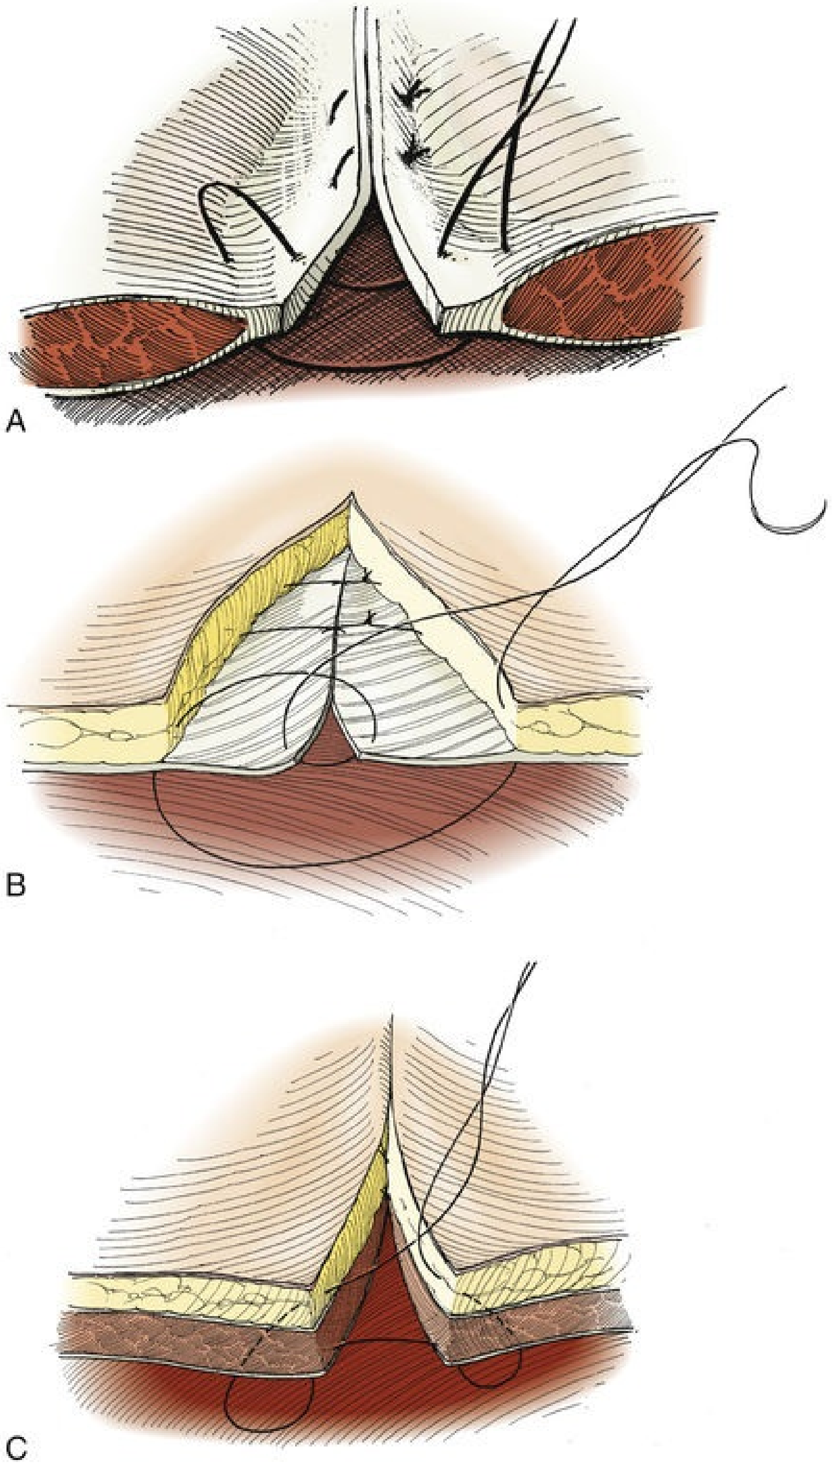

FIG. 9.3 Other fascial closure techniques. Different fascial closure techniques have been described but are less commonly used by urologists. In this figure, we see (A) near-and-far suture for mass closure, (B) Smead-Jones technique in which sutures are 2 cm apart with near and far figure-eight bites, and (C) a Gambee stitch or vertical mattress that incorporates both fascial layers. (From Smith JA Jr, Howards SS, Preminger GM,

Dmochowski RR. *Hinman's atlas of urologic surgery*, 4th ed. Philadelphia, PA: Elsevier, 2018: Fig 2.7A–C.)

Pfannenstiel Incision

This incision is utilized by both adult and pediatric urologists and may be suitable for both extraperitoneal and intraperitoneal pelvic surgeries. It also serves well as a specimen-extraction site postnephrectomy (Matin and Gill, 2003) and may have lower rates of morbidity and incisional hernias than a midline or extension of a port site approach (Binsaleh et al., 2015; Lee et al., 2017).

A transverse semilunar incision is made two fingerbreadths above the pubic bone (Fig. 9.4). The anterior rectus sheath is opened transversely, and the muscle above and below either side of the midline is bluntly separated from the sheath. Using cautery or scissors, the linea alba attachment to the anterior sheath is taken down both inferiorly and superiorly. The midline is then opened to either expand into the extraperitoneal space (Space of Retzius) or enter the peritoneum. The incision can be extended laterally for more exposure and can be extended into a Gibson incision if one needs more access to the lower ureter, for example. For specimen extraction, it can be modified slightly toward the side of surgery (Matin and Gill, 2003). For closure, the peritoneum and muscle are reapproximated, and the fascia is closed with a running or figure-of-eight absorbable suture.

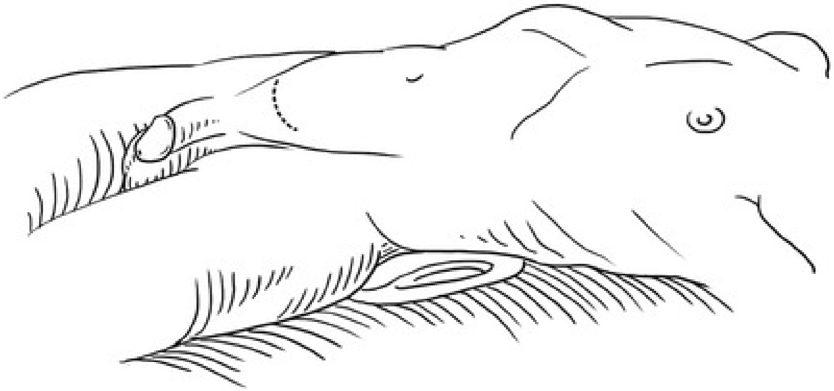

FIG. 9.4 Pfannenstiel incision. A Pfannenstiel is most commonly used by urologists for benign and malignant pelvic organ procedures in pediatric and adult populations. It can also be used for donor nephrectomy and specimen extractions. It heals well cosmetically and has decreased pain

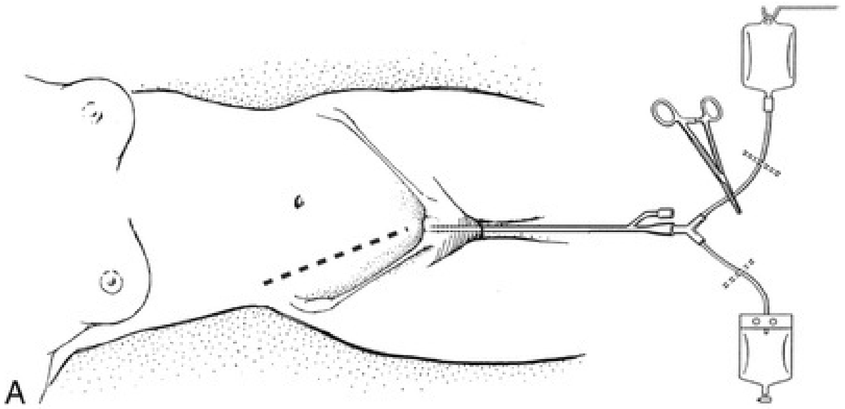
postoperatively because it is a muscle-splitting procedure. (From Smith JA Jr, Howards SS, Preminger GM, Dmochowski RR. *Hinman's atlas of urologic surgery,* 4th ed. Philadelphia, PA: Elsevier, 2018; Fig. 69.1.)

Gibson Incision

The Gibson incision is the traditional approach for renal transplant and transplant nephrectomy (Wagenaar et al., 2017). This muscle-splitting incision provides great extraperitoneal access to pelvic vessels, the lower ureter, and the bladder for benign and malignant disease and is also utilized as part of minimally invasive nephrectomy for specimen extraction or use of a hand port (Yang and Ou, 2012).

The traditional pelvic Gibson incision is an oblique or curvilinear incision from a few centimeters medial to the anterior superior iliac spine (ASIS) extending down toward the inguinal fold and terminating just lateral to the rectus muscle or continued to above the symphysis pubis (Graybar and Tarpey, 1987; Kahan, 2000). Recently, this incision has been modified to be more *J*-shaped or “hockey-stick” shaped (Fig. 9.5), although some retrospective comparisons have found this leads to higher hernia rates (Nanni et al., 2005). The external oblique muscle is split, followed by the internal oblique and transversus abdominus muscles in the same fashion. These can be incised if needed for further exposure. The peritoneum is then identified and mobilized medially to maintain an extraperitoneal approach. The ureter can be then identified crossing the iliac artery. Alternatively, the peritoneum can be opened if this incision is being used for a hand port in a laparoscopic procedure. This incision is usually closed in two layers with running absorbable sutures.



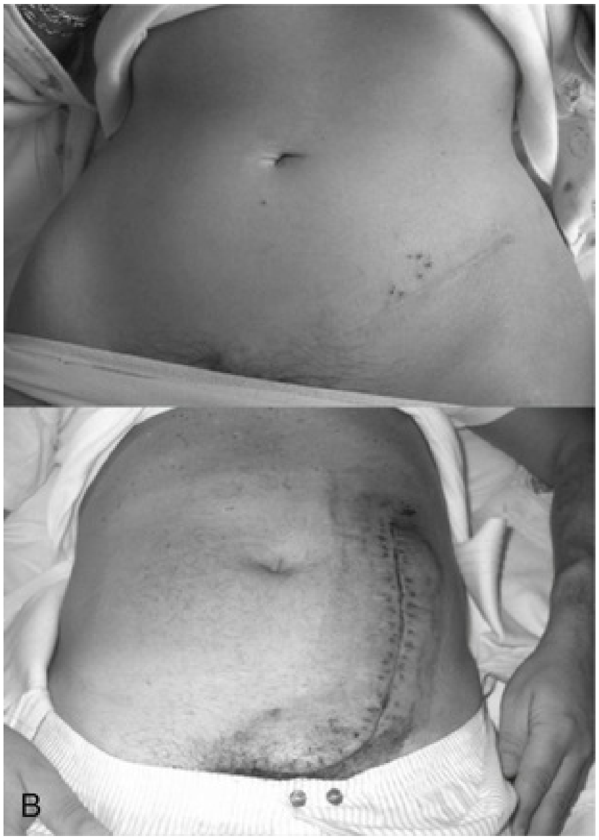


FIG. 9.5 (A) Traditional oblique Gibson incision. The traditional Gibson incision is shown here. This incision is used for renal transplantation and allograft nephrectomy as well as access to the lower ureter and bladder. (B) Traditional oblique Gibson vs. "hockey-stick" incision. The modern Gibson incision has become practically more "*J*-shaped," now also called a "hockey-stick" incision by some. Both incisions serve a similar purpose, with the *J*-incision able to be extended more superiorly if needed. (A, From Smith JA Jr, Howards SS, Preminger GM, Dmochowski RR. *Hinman's atlas of urologic surgery,* 4th ed. Philadelphia, PA: Elsevier, 2018; B, From Nanni G, Tondolo V, Citterio F, et al. Comparison of oblique versus hockey-stick surgical incision for kidney transplantation. *Transplant Proc.* 2005;37(6):2479–2481.)

Anterior Approaches to the Kidney and Retroperitoneum

Fig. 9.6 illustrates various midline and anterior incisions that are discussed in this chapter. These all provide access to the kidney or retroperitoneum with their own advantages and disadvantages (Table 9.1). The decision on which incision to use is based on oncologic and patient factors as well as surgeon preference.

FIG. 9.6 Anterior approaches to kidney and retroperitoneum. In a supine position, or modified oblique position, there are multiple approaches to the kidney and retroperitoneum anteriorly. These each have different benefits and disadvantages, which can be found in Table 9.1. (From Smith JA Jr, Howards SS, Preminger GM, Dmochowski RR. *Hinman's atlas of urologic surgery,* 4th ed. Philadelphia, PA: Elsevier, 2018; Fig. 8.4.)

TABLE 9.1

Open Approaches to the Kidney

APPROACH	INCISION	INDICATIONS	BENEFITS	LIMITATION
Anterior	Midline Transperitoneal	Trauma, IVC thrombus, bilateral renal or ureteral disease, horseshoe kidney	Rapid, less painful, can access both kidneys, early vascular control	Limited exposure to the upper retroperitoneu bowel complications, wound complications
	Subcostal	Radical nephrectomy, UPJO	Incision can be extended to chevron or flank, early vascular control	Bowel complications
	Chevron	Bilateral renal tumor, IVC thrombus, polycystic bilateral nephrectomy, local tumor extension or invasion	Excellent bilateral exposure, early vascular control	Injury to liver and spleen, transection of large muscles
	Transverse Abdominal	Pediatric Wilms tumor, pediatric pyeloplasty	Easy access to the renal pedicle and retroperitoneal nodes	Unfamiliar incision in adults
	Paramedian	Avoidance of another structure (e.g., colostomy)	Facilitates development of the preperitoneal space in the extraperitoneal approach	Risks injury to superior epigastric arter thoracic nerve hernia risk
	Modified Thoracoabdominal	Radical nephrectomy, lymphadenectomy, retroperitoneal mass	Versatile, exposure of large upper pole or adrenal masses	Bowel complications, transection of large muscles, painful, wound complication risk

Flank	11th or 12th Rib Supracostal	Partial nephrectomy, simple nephrectomy, simple adrenalectomy	Extraperitoneal with good renal and retroperitoneal exposure; avoids cutting rib	Pleural injury
	11th Rib Transcostal	Partial nephrectomy, simple nephrectomy, simple adrenalectomy	Good renal and retroperitoneal exposure	Pleural injury, flank bulge
	Thoracoabdominal	Large renal mass, IVC thrombus, adrenal mass, involvement of surrounding structures, lymphadenectomy	Excellent exposure, can approach completely extraperitoneally	Pleural injury, transection of large muscles, bowel complications intraperitoneal

IVC, Inferior vena cava; *UPJO,* ureteropelvic junction obstruction.

(Modified from Gregg JR, Scarpato KR. Surgical approaches for open renal surgery, including open radical nephrectomy. In: Smith JA Jr, Howards SS, Preminger GM, Dmochowski RR. *Hinman's atlas of urologic surgery*, 4th ed. Philadelphia, PA: Elsevier, 2018:61–75; Table 8.1.)

The transverse upper abdominal incision (incision 5 in Fig. 9.6) is more commonly used in pediatric renal surgery either for resection (e.g., Wilms tumor) or open reconstruction (e.g., pyeloplasty). Another incision less commonly used in the adult population is the paramedian incision. Although it has been described as an extraperitoneal approach for nephroureterectomy (Tessler et al., 1975) and pediatric bladder augmentation (Talic, 2000), a paramedian incision lateral to the rectus can risk injury to nerves within the rectus and predispose to ventral hernia (Chung et al., 2016), and it is therefore not performed often unless the surgeon would like to avoid entering midline because of a complex abdomen.

Thoracoabdominal Incision

With early incidental detection and nephron-sparing approaches becoming the norm, the indications for a thoracoabdominal incision have decreased. At the cost of a large and more morbid incision, it provides excellent exposure to the adjacent thorax, retroperitoneum, and great vessels, which allows for early vascular control (Buse et al., 2006). It can be utilized for more complex oncologic procedures, such as level III caval thrombus, T4 renal tumors, large upper pole tumors, adrenal tumors, and retroperitoneal masses (Parekh et al., 2005; Cooper et al., 1950). Somewhat contrary to what we believe as surgeons, a study comparing thoracoabdominal incisions with flank incisions found no difference in pain levels when patients were surveyed at different points within the first month of surgery (Kumar et al., 1999).

The patient is placed in an exaggerated flank position with the arm of the side being operated on elevated and secured to a mayo stand or trapeze. The incision is usually made above the 9th to 10th rib bed depending on the pathology, either supracostal or removing a section of rib and extended onto the abdomen. It can be extended to the midline in continuity if needed. Alternatively, a modified thoracoabdominal incision can be done by performing the thoracotomy through the 8th rib bed and combining a subcostal incision with the standard longitudinal abdominal incision (Merrill, 1977). The muscles are incised and the pleura opened with care not to injure the underlying lung. The diaphragm can then be opened to conjoin the thoracic and abdominal cavities and the costochondral junction cut (Chute et al., 1949).

The chest incision is closed after placement of a chest tube encompassing all the layers and reapproximating the cut edges of the costal cartilage, although some advocate that a chest tube can be omitted if there is no parietal pleural injury (Rosser et al., 2000). As part of this closure, the diaphragmatic incision is also closed in two layers with a running absorbable suture. Use of a nonabsorbable mesh (Marlex) with anchoring figure-of-eight sutures has been described to decrease costochondral displacement and discomfort (Stein and Skinner, 2002), although we have not adopted this in our practice. The abdominal wall is then closed.

Chevron and Subcostal Incisions

Use of a subcostal transperitoneal approach to the kidney can be utilized for addressing kidney masses with associated caval thrombus (Parekh et al., 2005). Alternatively, a supine subcostal incision may be used to address larger, more anterior tumors where access to the hilum may be better controlled than via a flank subcostal approach (Caraballo et al., 2018). A subcostal incision may be extended at the midline toward the xiphoid for better exposure of the suprahepatic vena cava or extended to incorporate a sternotomy if the thrombus has extended to the heart (Wotkowicz et al., 2006). This can further be extended across the midline as a full-chevron incision when a larger area of exposure is needed, such as with a caval thrombus extending from the left kidney or locally invading tumors (Pouliot et al., 2010) (Fig. 9.7).

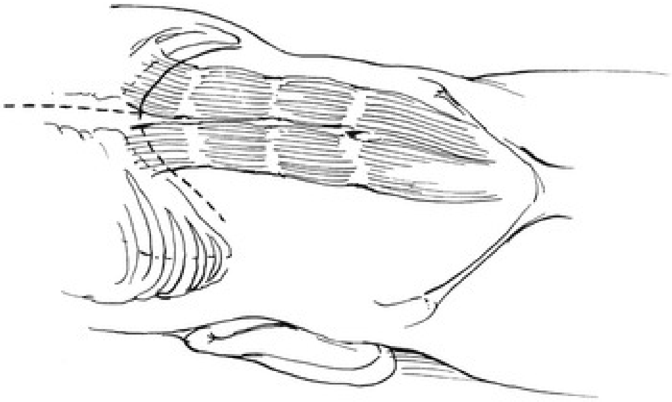

FIG. 9.7 Subcostal incision and extensions. The subcostal incision *(bold black line)* is shown on the left side. It can be used for renal access in the supine or flank position. *Dashed lines* represent possible extension across the midline to a "three-quarters" incision or complete subcostal "Chevron" incision. Further extension to include a sternotomy (shown with *dashed lines* as well) is rarely ever used by urologists. (From Smith JA Jr, Howards SS, Preminger GM, Dmochowski RR. *Hinman's atlas of urologic surgery,* 4th ed. Philadelphia, PA: Elsevier, 2018; Fig. 8.8.)

The patient may be in the supine or modified flank position. The incision is generally made from the midline two fingerbreadths below the costal margin extending laterally as far as the tip of the 11th rib. The anterior rectus sheath is incised, and the muscle is cut with electrocautery, while laterally the muscle layers are divided in sequence. This may be both an extraperitoneal or intraperitoneal incision, though generally the exposure is better with the latter. The retroperitoneum is exposed by incising along the white line of Toldt up to either the hepatic or splenic flexure and mobilizing the colon medially (Gregg and Scarpato, 2018). A self-retaining retractor such as a Bookwalter can be used to facilitate retraction and exposure, with care not to injure the liver or spleen. These incisions are closed in two layers with running absorbable sutures.

Flank Incisions

There are multiple flank and modified flank incisions used by urologists (Novick et al., 1998). Although careful technique can avoid the long-term complications and the postoperative pain traditionally associated with these incisions, they often still involve incision of muscles and/or removal of parts of ribs. Interestingly, some older comparisons have not shown them to be more painful than the thoracoabdominal approach (Kumar et al., 1999). Subsequently, in the era of minimally invasive surgery, they are commonly reserved for larger or complex oncologic resections. Based on surgeon skill and preference, these are still used around the world for benign renal surgery as well, including donor nephrectomy and simple nephrectomy for xanthogranulomatous pyelonephritis (XGP).

These incisions require dissection through three muscle/fascial layers: external oblique, internal oblique, and transversalis muscles. Muscle fibers are usually separated with electrosurgical cautery.

True Flank Incisions

Flank incisions are usually performed with the patient in the flank position, which is a lateral recumbent position with the lower leg flexed and upper leg extended, creating a convex extension of the upper side (operative side) of the body. The area of incision is placed over the break in the table to better “open” this area. Based on the target location and size of the renal or retroperitoneal mass, the traditional flank incision can be either 12th rib supracostal, 11th rib transcostal, or subcostal (Fig. 9.8). One usually begins anterior to the 12th rib laterally until no further than the medial edge of the rectus muscle medially (Gregg and Scarpato, 2018).

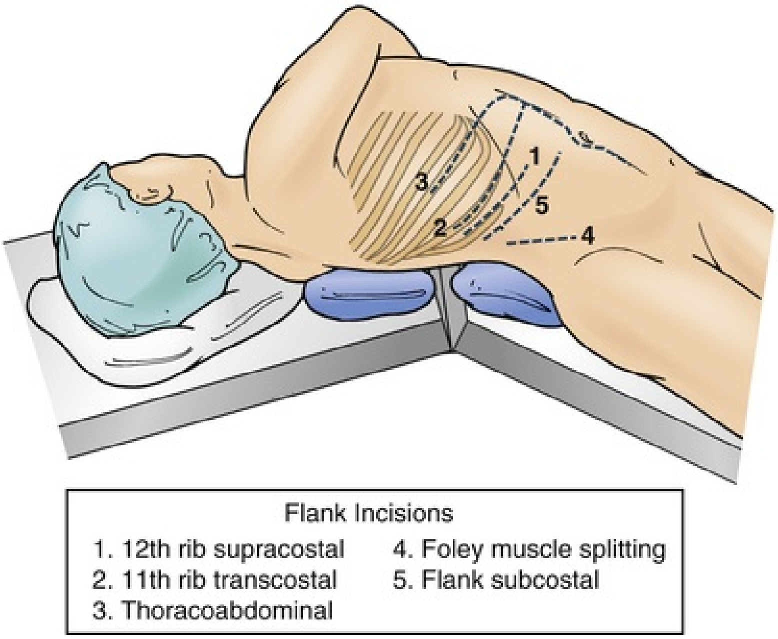

FIG. 9.8 Flank incisions for renal and retroperitoneal access. Commonly used incisions for renal and retroperitoneal access in the flank position. These incisions can be used for benign and malignant conditions. (From Smith JA Jr, Howards SS, Preminger GM, Dmochowski RR. *Hinman's atlas of urologic surgery,* 4th ed. Philadelphia, PA: Elsevier, 2018; Fig. 8.5.)

12th Rib Supracostal and 11th Rib Transcostal

These are the traditional flank incisions that often require taking the tip of the ribs using a rib cutter. They allow for more comfortable retroperitoneal access posteriorly, therefore decreasing the risk for associated bowel complications. However, they inherently increase the risk for thoracic complications including pleural injuries. Given the resection of the tip of the rib, patients will often have significant postoperative pain and a risk for a flank bulge if one goes as high as the 11th rib (Gregg and Scarpato, 2018).

The skin is incised over the rib and extended medially. Using electrocautery, the external oblique and latissimus dorsi are incised, centered over the rib to be extended past the tip of the rib onto the abdominal wall. Using a periosteal elevator, the muscle and the periosteum are stripped from the rib anteriorly and along the superior and inferior edges; a Doyen rib stripper is then passed posteriorly to free the rib, which can then be excised using a rib cutter. Sharp edges can be blunted with a the rib cutter or heavy scissors and sealed with bone wax. The rib bed is then divided, followed by the lumbodorsal fascia, and the pleura can then be identified by having the anesthesiologist give a series of larger-volume breaths. The retroperitoneum is then entered as posterior as possible with the peritoneum bluntly pushed medially as the remaining muscle layers are opened. The neurovascular bundle from either rib should be identified between the second and third layers and dissected free if possible. Retractors can then be placed.

The incision is traditionally closed in two layers with a running absorbable suture. In the event of a pleural injury, a red rubber catheter is placed through the injury, which is closed with a running absorbable suture. The diaphragmatic muscle layers are then closed. The catheter is placed in a bowl of water, and the anesthesiologist gives a series of high-volume breaths to force the air out of the pleural space. Once there are no more air bubbles, the red rubber tube is slowly removed. In the instance of a larger injury, a formal chest tube can be placed. A chest radiograph should be obtained postoperatively if a pleural tear was recognized and repaired, however it is not needed after every open nephrectomy as yield for pneumothorax is very low without clinical suspicion (Latchamsetty et al., 2005).

Alternatively, the incision can be made above the 11th rib or between the 11th and 12th ribs (Diblasio et al., 2006) and not excise the rib at all. This would avoid the complications and pain associated with rib resection and still allow for adequate exposure to the kidney and hilum (Fig. 9.9) (Gregg and Scarpato, 2018).

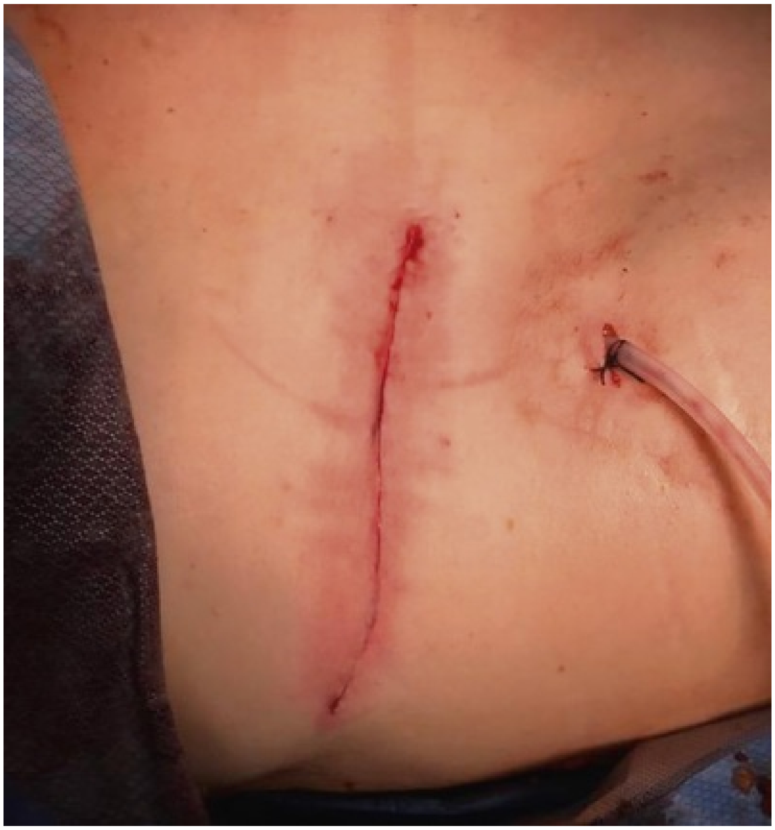

FIG. 9.9 Infra–11th rib incision with drain placement. This patient had a large right renal mass and our flank incision below the 11th rib. Use of a drain is not often required except when intra-operative findings mandate drainage of the nephrectomy site. Common scenarios would include partial nephrectomies or simple nephrectomies for XGP. By going supracostal (between 12th and 11th ribs), one can avoid cutting the rib tips and remain extraperitoneal.

Inguinal Incisions

There are multiple indications for utilizing inguinal incisions in both pediatric and adult patients. These procedures usually require access to the spermatic cord whether for the management of cryptorchidism and synchronous hernia repair or oncologic procedures such as partial or radical orchiectomy (Rice et al., 2016).

Incisions Above the Inguinal Ligament

The inguinal incision (Fig. 9.10) is used most commonly for radical orchiectomy in the adult population. A 5- to 7-cm curvilinear or transverse incision is made beginning 2 cm cephalad and lateral to the pubic tubercle. The angle can be made more oblique and extended toward the scrotum for larger scrotal masses.

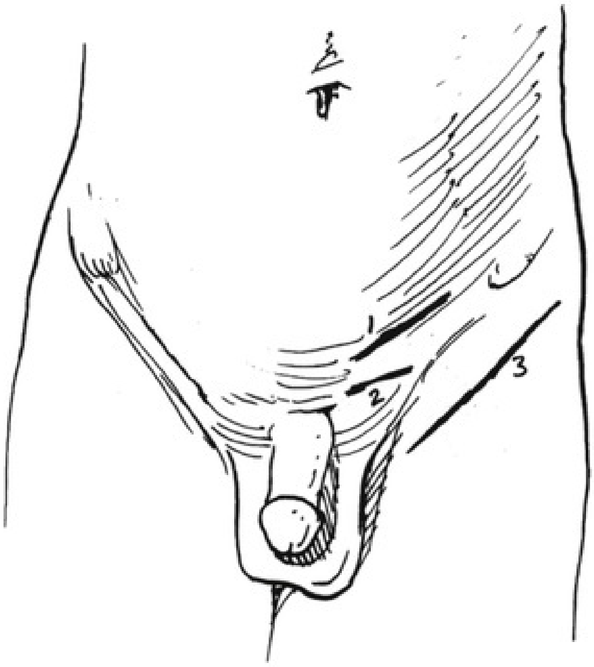

FIG. 9.10 Inguinal incisions. Incision 1: Curvilinear incision for radical orchiectomy and suspected malignancies. Incision 2: Inguinal incision above external inguinal ring for cryptorchidism or inguinal approach to varicocelectomy. Incision 3: Subinguinal incision for inguinal lymphadenectomy for penile cancer. (Modified from Smith JA Jr, Howards SS, Preminger GM, Dmochowski RR. *Hinman's atlas of urologic surgery,* 4th ed. Philadelphia, PA: Elsevier, 2018; Fig. 117.1.)

A similar incision can be used for inguinal varicocelectomies (especially in prepubertal children) and exploration for cryptorchidism (orchidopexy and hernia repair). For benign disease, the incision is usually smaller (2 to 3 cm) and begins two fingerbreadths above the symphysis pubis starting at the lateral aspect of the scrotum obliquely along the course of the inguinal canal. The goal in these benign operations is to enter just below the external inguinal ring, which can often be palpated externally in thinner patients and children (Marmar et al., 1985). A subinguinal approach can used in obese men or those with prior inguinal surgeries (Goldstein, 2016).

For incisions above the inguinal ligament, careful dissection is essential to avoid injury to the ilioinguinal nerve and spermatic cord structures (Goldstein, 2016). When closing these incisions, the internal and external oblique muscles should be reapproximated to close the inguinal canal and create a new external ring. One must be careful not to make the closure too tight, especially at the external ring, to ensure cord structures are not compromised (Turek, 2018).

Incisions for Inguinal and/or Pelvic Lymphadenectomy in Penile Cancer

Multiple incisions have been described for this purpose (Fig. 9.11). Extent of positive disease or desired dissection will determine which incision is performed. They can be used unilaterally for an extended or modified inguinal lymphadenectomy. The standard is a much larger incision and is associated with significant complications, including wound infection and lymphoceles (Protzel et al., 2009). Although other incisions are used for inguinal and pelvic lymphadenectomies (Gibson, *S*-shaped, *T*-shaped, elliptical), the basic subinguinal incision parallel to the inguinal ligament (Fig. 9.12) is most common and is used exclusively in urology for lymph node dissection and extensive penile cancer metastasis (Horenblas, 2001; Loughlin, 2006).

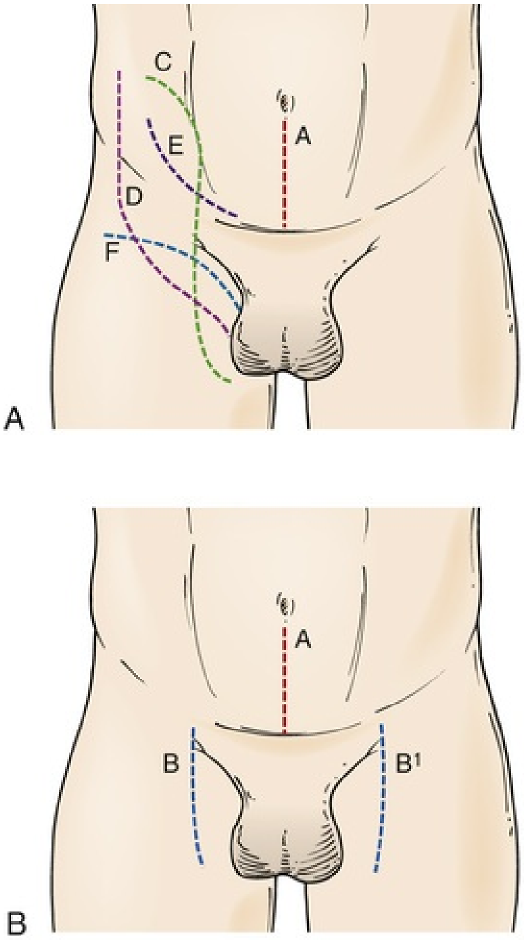

FIG. 9.11 (A) Various incisions described for ILND/PLND in penile cancer. *A*, Midline incision for bilateral PLND. *B*, Vertical incision allowing for access to superficial and deep ILND. *C, S*-shaped incision described for access to complete ILND and ipsilateral pelvic nodes. *D*, *L*-shaped incision for palpable disease, similar access to *C*. *E*, Gibson incision for ipsilateral pelvic node access. *F*, Common subinguinal incision for ipsilateral nodes. (B) Another approach for bilateral complete inguinal and pelvic lymphadenectomy. (Modified from Loughlin KR. Surgical atlas. Surgical management of penile carcinoma: the inguinal nodes. *BJU Int*. 2006;97(5):1125–1134.)

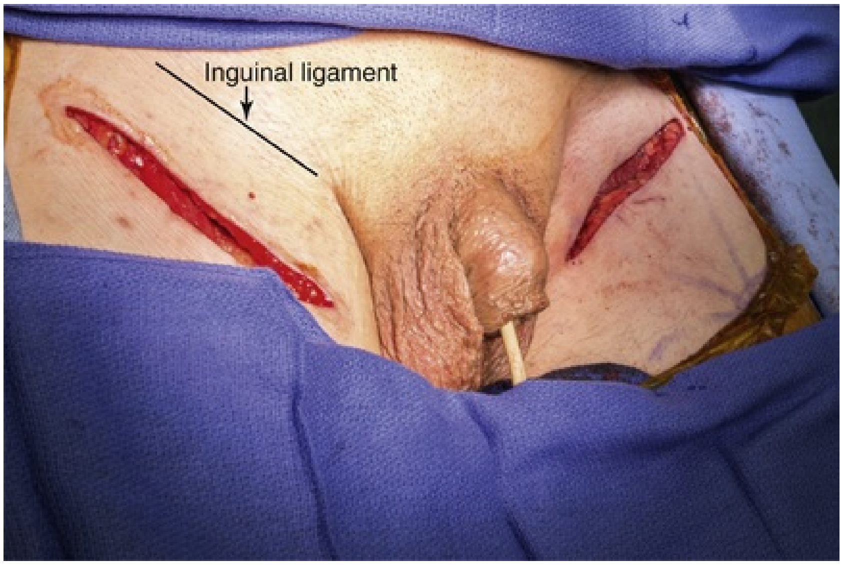

FIG. 9.12 Bilateral ilioinguinal lymph node dissection through subinguinal incision. This is the most common approach to an ilioinguinal lymph node dissection for penile cancer as it allows for a modified or complete lymphadenectomy. (From Smith JA Jr, Howards SS, Preminger GM, Dmochowski RR. *Hinman's atlas of urologic surgery,* 4th ed. Philadelphia, PA: Elsevier, 2018; Fig. 133.3.)

Typically, the skin is incised obliquely from the ASIS to the pubic tubercle 2 cm below the inguinal ligmanet parallel to the groin crease. The incision can be made elliptical if there is palpable or extensive disease superficially. Subcutaneous flaps are then developed below Scarpa's fascia to allow for the dissection of all the nodes in the region. Depending on the extent of disease and resection, closure may require a myocutaneous flap. The dissection and creation of flap are beyond the scope of this chapter. Fig. 9.12 shows bilateral inguinal node dissection incisions.

Incisions for Specific Surgeries

Posterior Lumbodorsal Incision or Dorsal Lumbotomy

Traditionally, the lumbodorsal approach to the kidney was used as it had multiple benefits over the flank incision (lack of muscle or rib distortion) and the anterior transabdominal approaches (faster convalescence and decreased intraperitoneal complications). Simon performed the first planned nephrectomy through this incision in 1870 (Hudnall et al., 1988).

Prior to the adoption of minimally invasive approaches, this incision allowed for good exposure, less postoperative pain, decreased hospitalization, more rapid convalescence, and ease of closure—advantages now boasted by laparoscopy and robotic surgery. The major disadvantages were the limited surgical exposure, which resulted in difficult access for vascular control of the kidney. Classically this incision was used for benign surgeries in adult and pediatric populations such as open upper tract urolithiasis, open renal biopsy, and pre-transplant nephrectomies. In modern times, this incision is mostly used for pediatric (Kumar and Smith, 1999) and sometimes adult (Troxel et al., 2006) pyeloplasty, although some advocate it is underutilized and can be modified for complex benign renal, adrenal, and renovascular surgery (Wollin and Menon, 1991). The incision itself is muscle sparing and has minimal risk for complications. Traditional contraindications to this incision included malrotation of the kidney, renal fusion abnormalities, severe spinothoracic deformities, and malignancy (Wollin and Menon, 1991). However, with recent emphasis on nephron-sparing surgery for renal masses, some groups have explored this incision for partial nephrectomies, boasting shorter operative times and reasonable surgical success, although oncologic outcomes were not assessed (Tennyson et al., 2016).

The lumbodorsal region is bordered between the 12th rib superiorly, iliac crest inferiorly, spinous processes of the vertebral column medially and laterally to an imaginary line between the ASIS and the costal margin (Wollin and Menon, 1991). Appropriate positioning for this procedure is essential with a laterolateral axis of 45 degrees and muscles relaxed to allow for easier retraction (Fig. 9.13).

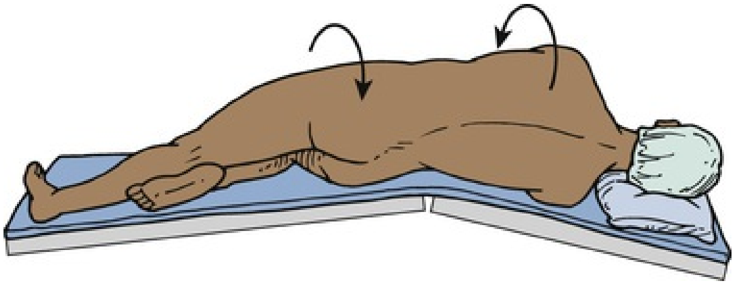

FIG. 9.13 Positioning for dorsal lumbotomy position. The position of the patient on the operating table is important and is characterized by three main features. The laterolateral axis makes a 45-degree angle with the operating table. It is not necessary for the table to be bent too much because the muscles do not need to be stretched; on the contrary, it is better if they are relaxed to allow easier retraction. The thorax is turned ventrally and the pelvis dorsally to allow a better opening of the dorsolumbar space. The legs and the upper arm are positioned as usual for a flank incision. (Modified from Pansadoro V. Surgery illustrated: Surgical atlas: The posterior lumbotomy. *BJU Int.* 2005;95[7]:1121–1131.)

Multiple incisions have been described (Hudnall et al., 1988; Pansadoro, 2005). The general approach is to start two to three fingerbreadths lateral to the spine with a 3- to 5-cm incision starting at the costovertebral angle or as high as the 11th rib. The incision is made directly over the quadratus lumborum muscle over the lateral part of the sacrospinalis muscle slightly obliquely toward the iliac crest or sacroiliac joint (Fig. 9.14). The superficial muscles encountered are the sacrospinalis (medially), latissimus dorsi (posteriorly), and external oblique (anteriorly). The incision is deepened through the lumbodorsal fascia, where the sacrospinalis muscle is encountered, and a “Y” should be made around it. This incision can be extended by transsecting the costovertebral ligament, mobilizing the 12th rib, and removing a 2-cm section of the 12th rib as needed.

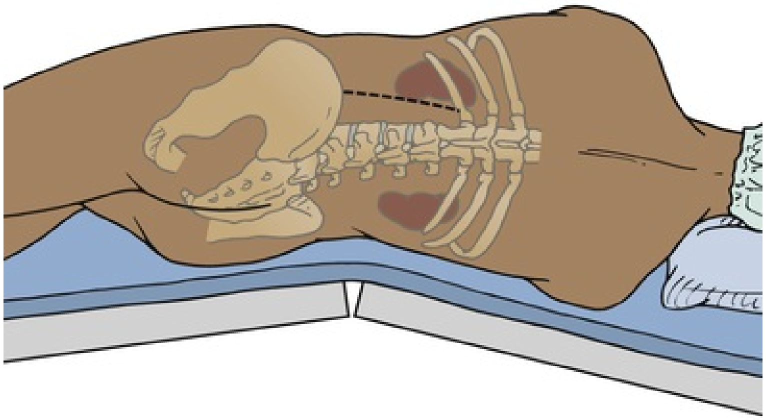

FIG. 9.14 Lumbodorsal incision. Once the iliac crest, the 12th rib, and the spinal processes have been located, the sacrospinalis muscle can be identified easily and the surgeon can then locate the quadratus lumborum. This muscle goes from the medial part of the 12th rib to the middle third of the iliac crest; its upper third is under the sacrospinalis muscle. The skin incision is made over the quadratus lumborum muscle and begins at the costovertebral angle, over the lateral part of the sacrospinalis muscle, and with a slightly oblique course extends down to the iliac crest, 3 to 5 cm in front of the anterior margin of the sacrospinalis muscle. (Modified from Pansadoro V. Surgery illustrated: Surgical atlas: The posterior lumbotomy. *BJU Int.* 2005;95[7]:1121–1131.)

Although largely replaced by abdominal or flank approaches, the posterior lumbodorsal approach to the adrenal glands can also be achieved in a similar fashion in a prone position. These can be used for bilateral extraperitoneal access to the adrenal glands (Young, 1936) or unilateral access through an incision over the 12th rib, the 11th rib, or the classic lumbodorsal incision (Vaughan and Phillips, 1987; Vaughan, 1991) (Fig. 9.15).

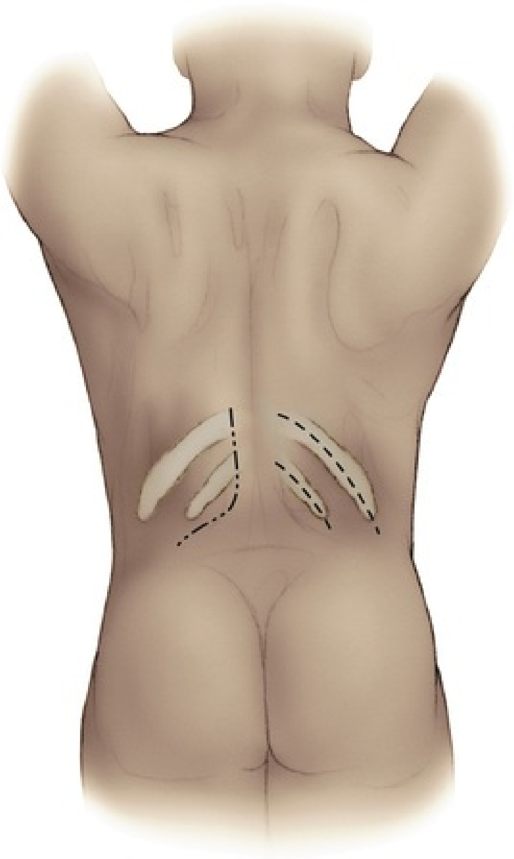

FIG. 9.15 Unilateral or bilateral posterior lumbodorsal incisions. These incisions can be performed in a prone position to access the adrenal glands unilaterally or bilaterally.

Scrotal Incisions

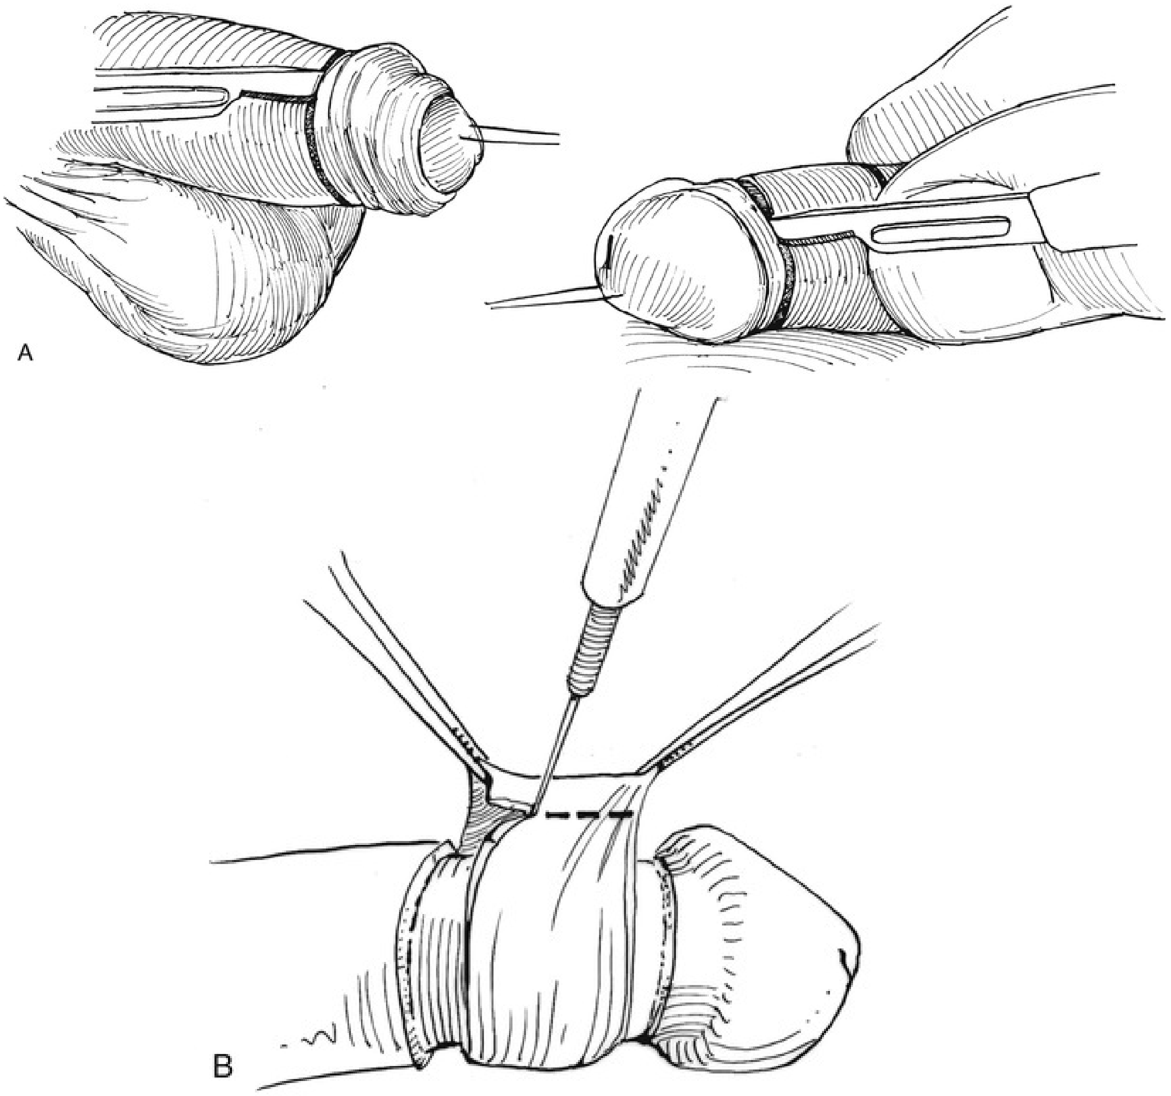
There are various approaches to scrotal procedures. Scrotal skin is quite elastic, and incisions are easy to close. The only contraindication to a scrotal incision is presumed testicular or intrascrotal malignancy, which should be approached through an inguinal incision (Rice et al., 2016). Depending on the indication, a unilateral incision can be used in a transverse or vertical approach on the ipsilateral side. If there is desire to operate on both sides of the scrotum, then a midline vertical incision is made in the median raphe. Common indications include varicocelectomy, hydrocelectomy, spermatocelectomy, vasectomy, scrotal exploration for testicular torsion, and orchidopexy (Dayanç et al., 2004). One can also reach the base of the penis to insert an inflatable penile prosthesis or artificial urinary sphincter through a scrotal incision (Rolle et al., 2012).

Given the elasticity and rich blood supply of the scrotum and scrotal structures, usually an effort is made to close dead space to prevent swelling/hematoma formation. Alternatively, a Penrose drain can be left in temporarily. Closures usually involve one or two layers involving the dartos layer with an absorbable suture. The skin is closed in an interrupted or horizontal mattress fashion.

Penile Incisions

Penile incisions are usually performed electively for correction of Peyronie disease and are beyond the scope of this chapter. However, every urologist should have an approach to circumcision, penile fractures, and distal shunts for priapism.

Pediatric circumcision is discussed later in this text. There are many approaches to circumcision, with the most common in adults being the two-incision “sleeve” technique (Fig. 9.16). First, retract the foreskin and mark out your first incision circumferentially about 5 to 10 mm from the edge of the glans, being careful not to be too close to the glans. Then replace the prepuce over the glans, and mark your second incision circumferentially on the prepuce at the coronal sulcus (visible through the prepuce) (Wan and Kraft, 2018). Check both of these markings again, and then very carefully cut both incisions using a #15 blade or preferred scalpel with extra caution around the frenular vessels. Either incision can be cut first, however we usually cut the prepucial incision (around the coronal sulcus) first. A space is then developed between the prepuce and the dartos/penile shaft, and the prepuce is cut longitudinally and removed. Hemostasis is of utmost importance given the rich blood supply and potential for significant hematomas and complications. Closure is usually done in a simple interrupted fashion with a 3-0 or 4-0 absorbable suture such as chromic gut. A continuous closure can also be performed with the same suture, but extreme care must be taken to not strangulate the tissue.



A
B

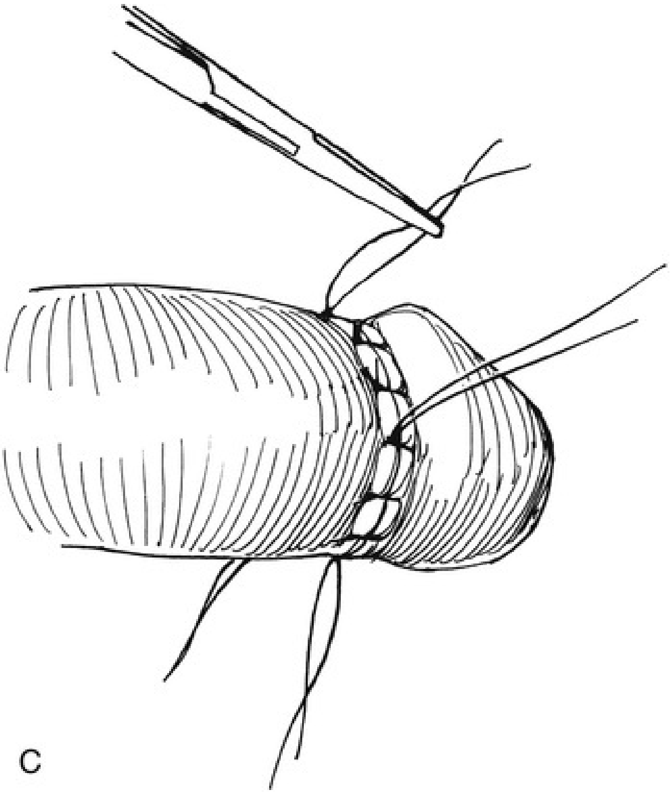


FIG. 9.16 (A to C) Circumcision. Adult circumcisions are most commonly done through the two-incision “sleeve” technique. Circumferential incisions are shown here on either side of the prepuce. The collar of skin is then isolated and cut longitudinally. Closure is performed in an interrupted fashion after hemostasis is achieved. (From Smith JA Jr, Howards SS, Preminger GM, Dmochowski RR. *Hinman's atlas of urologic surgery,* 4th ed. Philadelphia, PA: Elsevier, 2018; Figs. 120.1, 120.2, and 120.3.)

Suspected penile fractures and injuries are usually explored via a “degloving” approach. This approach begins with a circumferential subcoronal incision, similar to that in a circumcision or plication surgery for Peyronie disease (Reed-Maldonado and Lue, 2018). The penile skin is then carefully peeled back to expose the corporal bodies and allow for exploration for the suspected defect. The direct longitudinal incision might become more popular in the future compared with the degloving approach. A direct incision requires preidentification of the defect with imaging and was recently shown to have advantage over degloving in return to sexual function (Xu et al., 2016). Further details and images can be found in Chapter 133 of this text. The approach to distal penile shunts for priapism can be found in Chapter 70.

Perineal Incisions

Perineal incisions are most commonly used as an approach to the proximal urethra and base of the penis. Common indications include urethroplasties, perineal urethrostomy, male urethral slings, inflatable penile prostheses, and artificial urethral sphincters. Although rarely performed in modern times, this would also be the approach for radical perineal prostatectomy.

For urethral procedures, an 8- to 10-cm incision is performed vertically beginning at the perineoscrotal junction. An inverted-Y, or Lambda incision is also an option, however, this was recently shown to be associated with higher 90-day wound complication rates compared with a standard midline (Bascom et al., 2016). Closure is usually multilayer depending on the extent of dissection and mobilization. The Colles fascia should be closed before the skin closure, usually in a continuous fashion, to close the dead space and approximate the skin. Skin closure is usually in an interrupted mattress-type closure for approximation and to prevent opening of the incision given the location.

The radical perineal prostatectomy is done through a large inverted horseshoe incision. The apex of the incision is about 2 cm from the anal verge, and the ischial tuberosities are used as landmarks. Largely replaced by the retropubic prostatectomy, the details of the this approach are beyond the scope of this chapter. For more details, refer to *Hinman's Atlas of Urologic Surgery,* 4th edition, Chapter 77: Radical Perineal Prostatectomy (Smith et al., 2018). Interestingly, with the dawn of single-port robotic devices, this incision has recently been used to revisit the radical perineal prostatectomy and other urologic procedures (e.g., cystectomy, pelvic lymph node dissection) robotically through a perineal incision and might regain popularity in our careers (Akca et al., 2015; Kaouk et al., 2016; Maurice and Kaouk, 2017).

Key Points

- There remain several indications for open surgical approaches in urology. Decisions regarding open versus minimally invasive approaches depend on complexity/size of pathology, patient preference, and the surgeon's skill set.
- Knowledge of the abdominal wall musculature and anatomy are important to avoid key vessels and nerves when making incisions. These can usually be avoided by staying in the midline.
- Anterior abdominal incisions can be used to access pelvic, intraperitoneal,

retroperitoneal, and extraperitoneal structures. Urologists most commonly use a lower midline incision for access to the bladder and prostate.

- There are many open approaches to the kidney, each with their own advantages and disadvantages. Usually the kidney is approached via an anterior or flank incision, however dorsal incision was a traditional approach that is being explored again by some groups.
- Inguinal incisions can be above or below the inguinal ligament depending on the indication. They give access to contents of the spermatic cord, testicle, and ilioinguinal lymph nodes.
- Adult circumcisions are commonly performed through a two-incision technique on either side of the prepuce.
- Meticulous hemostasis is necessary for scrotal and penile incisions as one can have significant bruising and bleeding complications.
- Perineal incisions might become more common for various pelvic procedures with the development of new robotic technology.

Principles of Urologic Surgery

Intraoperative Technical Decisions

Manish A. Vira MD, Christopher J. Hartman MD

The perioperative management of patients undergoing urologic surgery continues to evolve. Over the past two decades, the economics of health care has added increasing pressure for more outpatient surgery, decreased hospital stays, and most importantly decreased complication rates. At the same time, the acuity of surgical patients has increased with patients who are older with more significant comorbidities. **The modern urologic surgeon is responsible for ensuring not only that the patient enters the operating room in the most optimized medical condition but also that the intraoperative decision making results in the best possible outcomes.**

Patient Environment

Patient Temperature

Although hypothermia can be therapeutic in certain situations of trauma and brain injury, for elective surgical procedures, hypothermia is associated with significantly increased morbidity to the patient. There are two primary reasons for hypothermia to develop in the operating room. First, anesthetic agents induce peripheral vasodilation redistributing heat from the core (trunk, head) with a resultant drop in immediate core temperature after induction. Second, heat loss occurs through radiation and conduction/convection throughout the procedure as the body interacts with air environment in the operating room. **Normothermia is defined as core temperature between 36°C and 38°C, and even changes of 1°C to 2°C can result in adverse effects.** Rajagopalan et al. (2008) performed a meta-analysis of randomized controlled trials (RCTs) and reported that mild hypothermia (decrease of 1°C) resulted in a 16% increase in estimated blood loss and a 22% increase in transfusion requirements. The increased bleeding risk is thought to result from a hypothermia-associated decrease in clotting cascade enzymatic function and platelet aggregation. Even more significant is the increase in the risk of surgical site infections (SSIs) associated with mild hypothermia (34°C to 36°C). Hypothermia increases the risk of SSI by impairing immune mechanisms and vasoconstriction, resulting in regional tissue hypoxia. In a landmark study, Kurz et al. (1996) with the Study of Wound Infection and Temperature Group tested the hypothesis that hypothermia increases the rate of wound infection and hospital stay in 200 patients undergoing elective colorectal surgery. **Hypothermia was associated with a three times increased risk of wound infection and a 2.6-day increase in hospitalization.** Subsequent studies have generally confirmed these findings in other series of surgical patients (Mauermann and Nemergut, 2006). In its overall goal of reducing SSI, the Surgical Care Improvement Project has also included perioperative normothermia as one of its guidelines. Strategies to improve maintenance of normothermia include regular use of warming blankets, warmed intravenous fluids, warmed irrigation fluids (especially during transurethral resection of the prostate [TURP] and other prolonged endoscopic procedures), warmed/humidified CO_2 gas during laparoscopy, and an increase in ambient operating room temperature. A recent Cochrane review confirmed the benefits of active body surface warming systems, citing beneficial effects of reduced rate of SSI, reduced major cardiovascular complications, decreased blood loss, and improved patient comfort (Madrid et al., 2016).

Skin Preparation

Sterile skin preparation is fundamental in the prevention of SSI for any procedure. Currently, the most commonly used skin antiseptics are alcohol, povidone-iodine, or chlorhexidine-based. Whichever antiseptic is chosen, the solution should be applied in concentric circles from the center of the surgical site and be allowed to dry before incision. The Cochrane Wound Study Group recently published their updated third analysis on various preoperative skin preparations (Dumville et al., 2015). The authors again were unable to report conclusive evidence of superior efficacy of one particular skin preparation. Furthermore, although the Centers for Disease Control and Prevention (CDC) clearly recommends preoperative showering/bathing to reduce SSI, there is no evidence that bathing with an antiseptic solution reduces the rate of infection (Webster and Osborne, 2007). Regarding hair removal, the CDC recommends that if hair removal is performed, it should be performed immediately before the surgical procedure and performed with clippers (rather than shaving) (Mangram et al., 1999).

Patient Safety

In 1991 Brennan et al. published their seminal work describing adverse events, defined as injuries caused by medical management in hospitalized patients, revealing that 48% of the events accompanied a surgical operation (Brennan et al., 1991; Leape et al., 1991). This important study inspired the publication of “To Err Is Human, Building a Safer Health System,” a comprehensive study by the Institute of Medicine on medical errors. Regarding surgical patients, the most frequent venue of preventable injuries is the operating room. Although the surgeon is the “captain of the ship” and ultimately responsible, it takes awareness of and attention to detail from each member of the operating room team to prevent iatrogenic injuries to the patient. **Three causes of immediately preventable injuries are retractor-associated injuries, thermal injuries, and patient position–related injuries.** There are several reports in the literature documenting increased rate of neuropathy (especially femoral nerve) after laparotomy with self-retaining retractors versus without self-retaining retractors (Irvin et al., 2004). **Careful attention to be certain that the lateral blades do not directly compress the psoas muscle and only cradle the rectus abdominal muscles ensures avoidance of femoral neuropathy.** Furthermore, periodic reinspection of the retractor blades is also warranted. Many devices used in urologic surgery employ thermal energy for desired effect and therefore can result in thermal injury to the patient. These include Bovie cautery, argon beam coagulator, bipolar devices, and laser. **In endoscopic and laparoscopic surgery, high-wattage light sources are used to illuminate the operative field. While illuminated, the ends of the light cords can result in burns when in direct contact with the patient (even through draping).** These light sources should be turned off at all times when not in use. Special mention is deserved for the morbidly obese patient. The operating room should be equipped with a hydraulic table, extra-long instruments, additional padding, wide venous compression devices, and side extensions to ensure a safe operating room environment for the patient.

Patient Positioning

Although often given only a cursory evaluation, proper patient positioning in the operating room can prevent potentially devastating complications. **Ultimately, proper positioning is the shared responsibility of each member of the operating room team.** Much of the knowledge and guidelines for avoidance of position-related injury are drawn from the anesthesia literature. In fact, in response to a 1999 study of the American Society of Anesthesiologists (ASA) Closed Claims Database, which found neuropathy as the second-leading cause of liability, the ASA published a practice advisory for the prevention of perioperative peripheral neuropathies (Practice advisory, 2000). The recommendations are listed in Table 10.1. **Although the exact mechanisms of peripheral neuropathy are not always known, the cause of position-related neuropathy is generally secondary to excessive stretch, prolonged compression, or ischemia.** Given the variety of different patient positions used in urologic surgery, it is critical for the urologist to be an active participant in the positioning of the patient and to understand the potential patient compromise that accompanies each position.

TABLE 10.1

American Society of Anesthesiologists Task Force Recommendation on the Prevention of Perioperative Peripheral Neuropathies

Preoperative assessment	• When judged appropriate, it is helpful to ascertain that patients can comfortably tolerate the anticipated operative position.
Upper extremity positioning	• Arm abduction should be limited to 90 degrees in supine patients; patients who are positioned prone may comfortably tolerate arm abduction greater than 90 degrees. • Arms should be positioned to decrease pressure on the postcondylar groove of the humerus (ulnar groove). When arms are tucked at the side, a neutral forearm position is recommended. When arms are abducted on armboards, either supination or a neutral forearm position is acceptable. • Prolonged pressure on the radial nerve in the spiral groove of the humerus should be avoided. • Extension of the elbow beyond a comfortable range may stretch the median nerve.
Lower extremity positioning	• Lithotomy positions that stretch the hamstring muscle group beyond a comfortable range may stretch the sciatic nerve. • Prolonged pressure on the peroneal nerve at the fibular head should be avoided. • Neither extension nor flexion of the hip increases the risk of femoral neuropathy.
Protective padding	• Padded armboards may decrease the risk of upper extremity neuropathy. • The use of chest rolls in laterally positioned patients may decrease the risk of upper extremity neuropathies. • Padding at the elbow and at the fibular head may decrease the risk of upper and lower extremity neuropathies, respectively.
Equipment	• Properly functioning automated blood pressure cuffs on the upper arms do not affect the risk of upper-extremity neuropathies. • Shoulder braces in steep head-down positions may increase the risk of brachial plexus neuropathies.
Postoperative assessment	• A simple postoperative assessment of extremity nerve function may lead to early recognition of peripheral neuropathies.
Documentation	• Charting specific positioning actions during the care of patients may result in improvements of care by (1) helping practitioners focus attention on relevant aspects of patient positioning and (2) providing information that continuous improvement processes can use to effect refinements in patient care.

The supine position, used in abdominal, pelvic, and penile procedures, is generally considered the safest patient position. However, several specific issues should be considered. Excessive upper extremity abduction (>90 degrees) can lead to tension on the brachial plexus, leading to upper extremity neuropathy. The armboard should be padded to avoid excessive pressure on the ulnar groove and spiral groove of the humerus (radial nerve injury). In cases in which the arms are tucked at the patient's side, care must be taken to avoid excessive pressure on the hand and forearm. Moreover, peripheral intravenous catheter infiltration must be identified quickly because forearm compartment syndrome may develop.

One of the most frequent positions used in urology is the lithotomy position. Improper positioning can lead to transient and occasionally prolonged lower extremity neuropathy. In a retrospective evaluation of more than 190,000 cases from 1957 to 1991 involving the lithotomy position, persistent neuropathy was found in 0.03%; however, the same group in a prospective study of 991 patients reported an incidence of 1.5% (15 patients) with resolution of symptoms by 6 months in all but one patient (Warner et al., 1994, 2000). **The basic principle of lithotomy position involves manipulation of both lower extremities simultaneously with flexion of the hips at 80 to 100 degrees with 30- to 45-degree abduction.** The legs should be padded to avoid excessive compression against the stirrup. Particular caution should be given to the patient's hands to avoid entrapment within the moving parts of the stirrups.

For most open and laparoscopic upper urothelial tract and renal procedures, the patient is placed in some degree of lateral decubitus position. Proper padding of the patient is important with appropriate anterior and posterior support to maintain the decubitus position. **The most frequent focus of compromise involves positioning of the arms and potential for brachial plexus injury.** The ipsilateral arm should be placed on an elevated arm rest or gel pad, avoiding abduction more than 90 degrees and excessive stretch on the shoulder. The contralateral arm should be placed on an armboard with ulnar padding. Furthermore, in patients in full flank position, an axillary roll should be placed just caudal to the axilla (not in the axilla) to avoid compression of the contralateral brachial plexus. Finally, after the patient is positioned and before sterile draping, the operating table should be fully rotated to ensure that the patient is adequately secured in all positions.

Two patient positions used in specific urologic cases deserve attention: the prone position for percutaneous nephroscopy and the full Trendelenburg position for robotic-assisted laparoscopic procedures in the pelvis. In the prone position, special care should be taken to pad the torso, elbows, hips, and legs. The anesthesiologist should ensure that the endotracheal tube and all vascular access are properly secured. Coordination of the entire team is required during transfer from the supine position on the stretcher to the prone position on the operating room table. A stretcher should always be available immediately in case of airway compromise and the need for rapid transfer to the supine position. Regarding the full Trendelenburg position for minimally invasive pelvic procedures, the primary issues involve the physiologic changes in respiratory function, cardiovascular function, and increases in central venous and intracranial pressures. **Patient positioning should focus on properly securing and padding the patient to the operating table to prevent cephalad sliding. Although fixed shoulder braces undoubtedly prevent patient movement, these braces should be avoided because of the risk of brachial plexus compression and resultant neuropathy.**

Blood Products

Packed Red Blood Cells

Given the vascular nature of urologic organs, the urologist often confronts the issue of indication and necessity of transfusion in the perioperative period. Therefore it is important that the urologist understand the indications, implications, and risks associated with blood product transfusion. Before the acquired immunodeficiency syndrome (AIDS) epidemic, blood transfusion was liberally administered often for any patient with hematocrit less than 30%. However, fear and concern about the infectious risk led to the convening of a National Institutes of Health (NIH) panel to develop consensus recommendations for the indication of blood product transfusion (NIH Consensus Statement, 1988). The principles in these guidelines remain current, as reflected by the ASA practice guidelines issued in 2006 (Practice guidelines, 2006) and updated in 2015 (Practice guidelines, 2015). **To summarize, the guidelines indicate that transfusion is rarely indicated with hematocrit greater than 30% and often indicated for hematocrit less than 21%. For levels between 21% and 30%, clinical factors such as risk of complications from inadequate oxygenation should guide the need for transfusion, balancing the risks and benefits.** In general, patients with relatively minor comorbidities can tolerate hematocrit of greater than 21% before transfusion is indicated. Patients with moderate to severe comorbidity (i.e., with significant pulmonary compromise, coronary artery disease, or vascular insufficiency or with signs/symptoms of hypovolemic or hemorrhagic shock) warrant transfusion to achieve hematocrit greater than 30%. The guidelines updated in 2015 included recommendations to consider intraoperative antifibrinolytic therapy (tranexamic acid, epsilon aminocaproic acid) in situations with anticipated excessive blood loss such as cardiac and liver surgery.

Component Therapy

A major advance in blood banking and product transfusion has been the development of component therapy, allowing for administration for specific fractions of whole blood. Packed red blood cells (PRBCs) are equivalent to whole blood minus the plasma component. Whereas the hematocrit in whole blood is 40%, it is 70% in PRBC units. These units are reconstituted and administered with crystalloid. Given the lack of the remaining components, in instances of massive PRBC transfusions and associated bleeding, platelets and occasionally fresh frozen plasma (FFP) should be given to avoid dilutional coagulopathy. **Platelet transfusion is rarely indicated empirically except in patients with significant thrombocytopenia (<50,000/mm^3) and planned surgical procedure or with moderate thrombocytopenia (50,000–100,000/mm^3) and either high-risk procedure or evidence of platelet dysfunction.** Similarly, empiric transfusion with FFP for massive transfusion is not indicated. With the development of component therapy, the use of FFP increased dramatically, leading to consensus statements from the NIH and the ASA to guide practitioners (Consensus conference, 1985; Practice guidelines, 2006). **The current indications for FFP transfusion are immediate reversal of anticoagulant medication-induced coagulopathy, replacement in patients with specific clotting factor deficiencies, and evidence of bleeding and international normalized ratio (INR) greater than 1.5.** According to the ASA guidelines, in patients with significant blood loss and no INR readily available, FFP should be given after replacement of 1 blood volume.

Massive Transfusion Protocol

Although very high blood loss procedures in urology are uncommon, given the proximity of major vascular structures to several genitourinary organs, occasionally the urologist is faced with a clinical situation in which transfusion of a large amount of blood is necessary. Traditionally, component transfusion would not begin until more than 6 units of PRBC had been given to the patient. **More recently, evidence from the trauma literature supports the use of increased ratio of platelet:FFP:RBC ratio (i.e., massive transfusion protocol). The protocol is triggered in the anticipation of greater than 10 units of PRBC in 24 hours and mobilizes blood bank and hospital resources to provide adequate supply of red blood cell and component transfusion.** There are multiple reports of improved survival of trauma patients managed with massive transfusion protocols. A study from Ball et al. (2013) demonstrated improved abdominal wall closure rates among patients with high-grade liver injuries when massive transfusion protocol was used.

Hemostatic Agents

Numerous different agents have been developed to aid in surgical hemostasis. These may be categorized as being derived from human-, animal-, or plant-based sources and may occur in either a dry or liquid form. In most cases, hemostatic agents act by enhancing local clotting factors and promoting blood clotting. They are not a substitute for good surgical hemostasis and typically do not seal large vascular defects, but they may be especially helpful as an adjunct in controlling slow bleeding from raw tissue surfaces.

Dry Matrix Agents

Dry matrix agents may be broadly categorized as oxidized regenerated cellulose, microfibrillar collagen, absorbable gelatin matrix, and microporous polysaccharide spheres. In general, they are less expensive than biologically active agents, typically costing between $50 and $100 per use, as compared with $300 to $750 for biologically active agents.

Oxidized regenerated cellulose agents (Fibrillar [Ethicon, Neuchâtel, Switzerland], Surgicel [Ethicon, Neuchâtel, Switzerland], Nu-Knit [Ethicon, Neuchâtel, Switzerland]), are plant-derived agents supplied as a mesh sheet. They work by activating the body's natural clotting cascade, thereby aiding in natural blood clotting. Placed directly on an area of bleeding, they may serve as a substrate on which a thrombus can form. Because of the pliable nature of the material, they are easily placed through laparoscopic ports and therefore can be used in open and laparoscopic surgeries. These agents typically dissolve within 1 to 2 weeks (Mannucci, 1998).

Microfibrillar collagen (Avitene [BD/C.R. Bard, Flanklin Lakes, NJ]), as its name suggests, is a bovine-derived collagen agent that is supplied in either a sheet of material or dense powdered form. When placed directly on a site of bleeding, it stimulates blood clotting by allowing proteins of the clotting cascade and platelets to adhere to it. **Because it works by enhancing platelet aggregation, its efficacy is decreased in patients with thrombocytopenia.** Microfibrillar collagen is completely absorbed within 12 weeks (Peralta, 2018).

Absorbable gelatin matrix agents (Surgifoam [Ethicon, Neuchâtel, Switzerland], Gelfoam [Pfizer, New York, NY]) are porcine-derived collagen agents packaged as a dry, pliable foam material. They are typically moistened with saline before use and are easily molded to conform to small

spaces. In addition, they can be placed through laparoscopic port sites during minimally invasive surgeries. Similar to other dry matrix agents, they promote the clotting cascade and act as a substrate on which a thrombus can form. They typically dissolve in 4 to 6 weeks and have been suggested to increase the risk of infection at the surgical site, possibly before their prolonged dissolution time and favorable substrate for bacterial adherence (Hong and Loughlin, 2006; Mannucci, 1998).

Microporous polysaccharide spheres (Arista [BD/C.R. Bard, Flanklin Lanks, NJ]) are derived from plant-based starch material and are available as a fine powder. This allows for broad coverage of the operative site by spraying the powder onto the field through an accordion-type bulb. Applicators can be either short or long and therefore can be placed through laparoscopic port sites. **Microporous polysaccharide spheres work by absorbing blood, thereby concentrating platelets and proteins of the clotting cascade.** They typically dissolve within 1 to 2 days of application (Ereth et al., 2008).

Biologically Active Agents

Biologically active agents can be characterized as topical thrombin agents, fibrin sealants, and tissue adhesives. They are usually delivered via a syringe and needle type applicator and may have to be mixed before application. In addition, they may be combined with a gelatin matrix to aid in hemostasis.

Topical thrombin agents (Thrombin-JMI [Pfizer, New York, NY], Evithrom [Ethicon, Neuchâtel, Switzerland], Recothrom [Malinckrodt Pharmacetuicals, Bedminster, NJ]) are human- or bovine-derived liquid agents that are applied directly to a site of bleeding. Floseal (Baxter, Deerfield, IL) and Surgiflo (Ethicon, Neuchâtel, Switzerland) are commonly used preparations of thrombin sealants that are combined with a gelatin matrix. **These hemostatic agents have the advantages in urologic surgery of not being inhibited by urine and of resisting stone formation within the urinary tract; therefore they are used commonly in urologic surgery** (Bak et al., 2004; Uribe et al., 2005).

Fibrin sealants (Tisseel [Baxter, Deerfield, IL], Evicel [Ethicon, Neuchâtel, Switzerland], Evarrest [Ethicon, Neuchâtel, Switzerland]) are human-derived liquid preparations of fibrinogen, factor XII, thrombin, and calcium. They are stored frozen and are thawed before use. A two-syringe system allows a preparation of fibrinogen and factor XII to be stored in one syringe, while thrombin and calcium are stored in another. When mixed via an applicator that combines the two solutions, a fibrin-based clot is formed over a site of bleeding. These agents are absorbed immediately and therefore pose a very low risk of infection at the surgical site (Mannucci, 1998; Peralta, 2018; Spotnitz and Burks, 2008).

Tissue adhesives (Bioglue) are bovine albumin-derived liquid agents that are effective for mild to moderate bleeding. **When administered over a site of bleeding, they form an adhesive matrix that causes hemostasis and may be effective when bleeding does not respond to other hemostatic agents.** They can be used to control bleeding from moderate-sized vessels (Chao and Torchiana, 2003; Pursifull and Morey, 2007).

Drains

A controversial issue in the prevention of organ and space infections is the routine placement of surgical drains at the time of an initial operative procedure. A wide variety of surgical drains are available. Drains are broadly categorized as open nonsuction, closed nonsuction, and closed suction drains. Open nonsuction drains are employed when accurate quantification of drainage amount is not necessary. These drains are associated with less patient discomfort and are the easiest to remove. Closed drains are chosen if quantification of drainage amounts or characterization of drainage fluid is necessary. The use of suction or negative pressure in closed drainage systems is preferred if immediate recognition of small amounts of drainage is important (e.g., a drain around the ureterointestinal anastomosis). **Although drains continue to be widely used in various urologic procedures, several prospective studies in the general surgical literature have failed to show significant benefit; therefore most experts caution against their routine use (unless strong indication exists)** (Barie, 2002).

Penrose

Penrose drains are soft, flexible latex or silicone rubber drains that allow passive drainage of fluid from a surgical site. They are available in a variety of sizes, typically ranging from ¼ inch to 1 inch in diameter, and can be cut to a desired length. Penrose drains are typically sutured to the skin to prevent drain migration either into or out of the wound. Penrose drains do not contain a collection system and therefore drain into the dressing material placed over an incision. Because of this, they may allow for an increased risk of infection at the surgical site and are therefore typically removed sooner than other closed drainage systems. Penrose drains are commonly used in scrotal surgery or may be placed in the subcutaneous tissue during wound closure to prevent fluid accumulation.

Jackson-Pratt

A Jackson-Pratt (JP) drainage system represents a closed drainage system. It consists of a grenade–shaped bulb that is connected to a flat or round perforated internal tubing system. The internal component of the tubing usually sits at the surgical site and can be tailored to the length and shape needed for a particular application. The external bulb is compressed to create negative pressure that draws fluid from the surgical site. **JP drains are commonly used during intra-abdominal urologic surgeries because they effectively remove blood, urine, and other fluids from the surgical field in the postoperative period.** As a closed drainage system, they minimize the risk of infection introduced by other open drainage systems. These drains are usually placed through a separate small incision away from the primary surgical site and are sutured in place to the skin. Removal of JP drains may cause discomfort because the perforated, collecting portion of the tubing is typically larger than the remainder of the drainage tubing.

Blake

Blake drains are similar to JP drains in that they are commonly used during intra-abdominal procedures to prevent postoperative fluid accumulation, contain a grenade-type external drainage bulb that creates negative pressure, and contain an internal tubing component that can be trimmed. **In contrast to JP drains, Blake drains consist of a continuous diameter tubing system that may minimize discomfort during removal.** In addition, as opposed to perforations that allow fluid entry into the tubing system, Blake drains contain channels that run the length of the collecting portion of the tube and allow fluid to enter via capillary action and negative pressure.

Pigtail

Pigtail drains are closed drainage systems that allow for drainage of a surgical site, abscess cavity, or organ space. They may be connected either to a negative pressure bulb, such as when draining an abscess cavity or surgical site, or to a drainage bag, as is common for nephrostomy tubes and suprapubic tubes. Pigtail drains contain a curled inner portion of tubing that is deployed by tightening a suture after placement. This curled portion contains small perforations for fluid removal and allows the drain to remain in position. Removal of a pigtail drain requires the suture to be loosened or the drain to be transected to unfurl the inner curled portion of the drain.

Suture Material and Incision Closure

Knowledge of the basic principles of wound healing is important to properly assess incision closure and its associated complications. **All cutaneous wounds progress stepwise through a series of events toward complete wound repair; in a particular wound, different phases of events may occur simultaneously. This series of steps can be divided broadly into three stages: reactive phase, proliferative phase, and maturational phase.** The reactive phase occurs immediately with the two primary responses of hemostasis and inflammation. Disruption of vascular membranes results in platelet activation and aggregation, which in turn initiate the inflammatory response. During this stage of wound healing, inflammatory cells, including polymorphonuclear cells, macrophages, and lymphocytes, migrate into the wound and become activated, leading to cytokine activation and secretion of various growth factors. The second stage, proliferative, results in the formation of granulation tissue. The stage is characterized by proliferation of endothelial cells and fibroblasts, leading to angiogenesis and epithelialization, which eventually results in growth of immature blood vessels and deposition of extracellular matrix and early collagen scaffolding. Finally, the maturation stage occurs with further deposition of collagen and wound contraction. **The maturational phase begins approximately 1 week after injury and progresses rapidly over 6 weeks, with increasing wound strength over the next 12 months.** The scar regains approximately 3% strength after 1 week, 20% after 3 weeks, and 80% after 3 months (Witte and Barbul, 1997).

Proper incision closure is necessary to avoid surgical complications, including wound infection, hernia formation, and fascial dehiscence. In general, there are three types of wound closure: primary, secondary, and tertiary (or delayed primary closure). In the majority of elective procedures, the urologist should attempt a permanent closure after the operation (primary closure). **Secondary closure is reserved for heavily contaminated wounds for which the fascia is closed primarily, but the skin and subcutaneous tissues are allowed to heal via re-epithelialization and contraction.** Tertiary closures are reserved for patients with abdominal compartment syndrome or patients requiring re-explorations, in whom temporary closure is initially performed with intention of future permanent closure. Unless the procedure involves heavy contamination, incision closure involves reapproximation of the fascia (in one or multiple layers) and the skin. **Choice of suture type by the urologist depends on preferences of braided versus nonbraided, monofilament versus multifilament, and absorbable versus nonabsorbable. A description of different suture types and their properties is listed in Table 10.2.**

TABLE 10.2

Properties of Suture Materials

SUTURE	ORIGIN	TISSUE ABSORPTION	PHYSICAL CONFIGURATION	TENSILE STRENGTH	COMMEN
Vicryl	Synthetic	Absorbable	Braided	65% 2 wk 40% 4 wk	Slower los function an higher kno breaking strength compared polyglycol acid (Dexo
Dexon	Synthetic	Absorbable	Braided	63% 2 wk 17% 3 wk	Lubricant coating decreases coefficient friction
Monocryl	Synthetic	Absorbable	Monofilament	30%–40% 2 wk (dyed) 25% 2 wk (undyed)	Excellent tensile strength allows use smaller sutures for skin closur
PDS	Synthetic	Delayed absorbable	Monofilament	74% 2 wk 50% 4 wk 25% 6 wk	No absorpt until after days; low reactivity, tends to maintain strength in presence o infection; newer barb version is

					knotless
Maxon	Synthetic	Delayed absorbable	Monofilament	81% 2 wk 59% 4 wk 30% 6 wk	
Chromic gut	Natural	Absorbable	Monofilament	0% 3 wk	Can also be found as pl gut (untrea for faster absorption
Nylon	Synthetic	Nonabsorbable	Monofilament	50% 1–2 yr	Very low tissue reactivity
Prolene	Synthetic	Nonabsorbable	Monofilament	No significant loss over time	High plasticity, extremely smooth surface (requires e knot throw
Silk	Natural	Nonabsorbable	Braided	Degraded over time	Braided fo easier handling; c be prone to infection
Mersilene	Synthetic	Nonabsorbable	Braided or monofilament	No significant loss over time	Braided should not used in infection

PDS, Polydioxanone suture.

An additional suture design developed in recent years is that of barbed sutures. These sutures contain small barbs that allow for increased tissue holding strength and prevent the suture from slipping backward in tissue. Barbed sutures are available as many different primary suture types, including Vicryl, polydioxanone suture (PDS), and Monocryl. They can therefore be used to reapproximate various different types of tissue, including skin, fat, fascia, and organs, and have been increasingly used in urologic surgery (e.g., vesicourethral anastomosis during prostatectomy).

Absorbable Sutures

Absorbable suture material has the advantage of providing sufficient tensile strength for wound closure, while dissolving over time. This latter property minimizes the amount of foreign body material in a wound, thereby decreasing the risk of infection. In general, absorbable sutures produce a greater inflammatory response than nonabsorbable sutures but do not need to be removed and therefore minimize additional wound trauma. The following is a brief review of commonly used absorbable sutures in urologic surgery.

Plain Gut and Chromic Gut

This suture material is made from the serosal lining of bovine or sheep intestine. Chromic gut suture is additionally processed with a chromium salt solution, which prolongs its tensile strength and reduces its rate of absorption. **Although these sutures are constructed as a monofilament, they have a much higher degree of friction than other synthetic monofilament sutures and therefore do not pass through tissue as easily. This allows the suture material to hold securely in tissue, as well as prevent it from unraveling in surgical knots.** Although chromic gut suture retains its tensile strength for 3 to 4 weeks, plain gut is restricted to 7 to 10 days, limiting its utility in most applications. These suture materials may be used to reapproximate the skin edges in areas of low tension in an interrupted fashion, such as that of the scrotal or penile skin.

Poliglecaprone (Monocryl), Biosyn, Caprosyn

These sutures are used primarily for subcuticular skin suturing and create minimal tissue reaction. Constructed as a monofilament, they create minimal trauma when passed through tissue. Monocryl creates acceptable tensile strength for 14 days, whereas Biosyn extends this time period slightly longer. **Caprosyn suture provides acceptable tensile strength for approximately 10 days, although it is absorbed in nearly half the time of the other two sutures and therefore theoretically reduces the risk of infection.**

Polyglactin 910; Vicryl

Vicryl suture is one of the most commonly used suture materials in intra-abdominal surgery and therefore should be familiar to urologists. This suture uses a braided design, although it easily passes through tissue and minimizes unraveling in surgical knots. Vicryl is commonly used to reapproximate subcutaneous tissue such as fat, muscle, and fascia and to create ureteroileal, ureterovesical, and other anastomoses.

Polydioxanone and Polyglyconate (Maxon)

PDS and Maxon suture are commonly used when an extended period of tensile strength is needed. Both sutures are constructed as a monofilament design and are available in a looped configuration for abdominal fascia closure. **PDS typically takes approximately 8 months to be fully absorbed, whereas Maxon is usually absorbed in approximately 6 months.**

Nonabsorbable Sutures

Nonabsorbable suture material has the advantage of retaining tensile strength for a longer period of time as compared with absorbable sutures. These sutures are not degraded by the body over time and therefore can act as a nidus for infection and stone formation. **For this reason, nonabsorbable sutures are not used when contact with urine is anticipated, such as during urinary tract anastomosis or repair of a genitourinary organ injury.** Although most nonabsorbable sutures provide an indefinite length of tensile strength, some nonabsorbable sutures, such as nylon and silk, gradually lose tensile strength over time. **In general, nonabsorbable sutures provoke less of an inflammatory reaction than absorbable sutures and therefore result in less discomfort when being removed.**

Polypropylene (Prolene)

Constructed as a monofilament suture, Prolene easily passes through tissue and creates minimal tissue reaction as it does. As compared with other nonabsorbable sutures, Prolene does not lose tensile strength over time and is therefore very well suited for areas where maximal strength is necessary, such as the abdominal fascia. **Because of its smooth surface and high plasticity, it has a tendency to unravel more than other suture types, and additional knot throws are necessary to ensure knot integrity.**

Polyester (Mersilene)

Similar to Prolene, Mersilene provides excellent tensile strength that does not degrade over time. As opposed to Prolene, it is constructed as a braided suture and therefore maintains better knot hold. **Because of this characteristic, however, it also allows for increased bacterial adherence and should not be used when concern for infection exists.**

Polyamide (Nylon)

Although nylon is a nonabsorbable suture, it does lose strength over time. It is commonly used as a drain suture because the smooth monofilament design passes easily through tissue and creates a minimal tissue reaction, therefore reducing pain as it is removed.

Silk

Constructed in a braided configuration, silk suture is effective at ligating large vessels. It provides a long duration of tensile strength and is not absorbed. This latter property makes it a favored suture type for cases in which wound reentry and easy suture location may be necessary, such as during inguinal orchiectomy.

Fascial Closure Techniques

Although numerous different abdominal fascial closure techniques have been described, a definitive, superior method has not been universally agreed upon. Most commonly studied has been closure in an interrupted fashion with absorbable suture, such as Vicryl, compared with closure in a continuous fashion with a slowly absorbing or nonabsorbable suture material, such as PDS, Maxon, or Prolene. van't Reit et al. (2002) performed a meta-analysis of available RCTs examining different fascial closure techniques. In all, 6566 patients from 15 studies were included; the primary outcome measure was incidence of incisional hernia. **The analysis demonstrated that between slowly absorbable and nonabsorbable suture material there was no difference in risk of incisional hernia in continuous versus interrupted fascial closures, although closure with nonabsorbable suture material was associated with increased wound pain and sinus formation.** For rapidly absorbable suture types, continuous fascial closure was significantly associated with an increased risk of incisional hernias. The authors therefore concluded that wound closure with slowly absorbable suture in a continuous fashion may be the preferred method of fascial closure. To address limitations encountered in previous meta-analyses, Seiler et al. (2009) performed an RCT of 625 patients undergoing surgery requiring fascial closure. Patients were categorized to one of three arms: interrupted fascial closure with rapidly absorbable suture or continuous closure with one of two different slowly absorbable sutures. They found no significant difference in the rate of incisional hernia formation (15.9% vs. 8.4% vs. 12.2%, $P = 0.09$), fascial dehiscence, wound infection, or serious adverse events between the groups. **In conclusion, although incisions may be closed in an interrupted fashion with more rapidly absorbable suture material or in a continuous fashion with slowly absorbable suture or nonabsorbable suture, careful attention should be paid to the technique of closure, given the relatively high incidence of incisional hernia formation.**

Perhaps the most dreaded complication of surgical incisions is acute wound failure (or fascial dehiscence). Overall the incidence of fascial dehiscence is 1% to 2%, and the complication usually occurs approximately 1 week after surgery (although it may occur up to 30 days postoperatively). Risk factors for dehiscence include patient-related factors (advanced age, malnutrition, corticosteroid use, obesity, and prior history of radiotherapy), SSI, and technical errors at the time of wound closure. **The most common technical errors associated with wound failure are placing sutures too close to the fascial edge, knot slippage, and excessive suture tension.** Multiple studies have investigated the type of fascial closure and have demonstrated that there is no difference in the risk of dehiscence between interrupted and continuous closures, as long as rapidly absorbable sutures are not used with the latter.

When acute wound failure does occur, it is usually immediately preceded by a sudden gush of serosanguineous fluid from the wound. **Some small fascial disruptions can be managed conservatively with wound packing and close observation, but the majority of disruptions, particularly in the setting of bowel evisceration, mandate urgent return to the operating room.** At the bedside, a sterile, saline-moistened towel should be placed over the eviscerated components while the patient is being prepared for the operating room. At the time of reoperation, the fascial edges are inspected for the cause of the disruption. In the case of a technical error or fascial tearing, in which the fascial edges are healthy and can be brought together without tension, a primary closure is appropriate. In all other cases, the fascial edges are debrided and the wound is closed with absorbable mesh or biologic prosthetic grafts. A full discussion of the different materials is beyond the scope of this chapter, but strong consideration should be given to an intraoperative general surgical consultation.

Skin Closure

The choice of how to close a skin incision depends on a number of factors, including the length of the incision, tensile strength the incision will be subjected to postoperatively, location of the incision, and need to reopen the incision in the future. Whereas Monocryl, Biosyn, and Caprosyn sutures are preferred for subcuticular suturing because of their ease of handling, minimal tissue reaction, and adequate strength to oppose wound edges, chromic sutures are often used to reappose the cut edges of skin after a circumcision or scrotal surgery because of its rapid time to dissolution and firm knot strength.

When a large abdominal or flank incision is closed, skin stapling offers an alternative to suturing an incision closed. Stapling an incision has the advantages of reduced time and effort to close an incision and the ability to open small areas of a wound should the need arise in the future, such as in the case of infection, while maintaining integrity of the remainder of the incision. Surgical staples, however, create a greater inflammatory tissue reaction and may cause more pain than subcuticular sutures. In addition, the need to remove staples and the discomfort at the time of their removal are averted when using absorbable suture material. **A recent meta-analysis involving 2111 patients comparing surgical staples with sutures for wound closure found that stapling an incision was, on average, 5.56 minutes faster than suturing an incision (Iavazzo et al., 2011). In addition, the authors found that wound infections were significantly more likely in incisions closed with suture than in those closed with staples (odds ratio 2.06).** Interestingly, the authors reported nonsignificant differences in cosmetic outcomes and patient satisfaction with wound appearance after closure with staples compared with sutures. These study results suggest that, although there is not a distinct advantage to closing skin incisions with either staples or suture, neither is inferior to the other, and the decision regarding the appropriate method of skin closure should be individualized on a case-by-case basis.

Retention Sutures

Historically, in high-risk patients retention sutures were strongly advocated and widely used as a preventive measure for wound dehiscence. Literature evidence, however, was primarily retrospective**. Subsequent prospective trials have since shown mixed evidence of benefit for preventing wound dehiscence (Carlson, 1997; Khorgami et al., 2013; Rink et al., 2000).** Specifically, Rink et al. (2000)

randomized 95 high-risk patients to retention sutures versus standard closure; the researchers reported that although no difference in wound failure rates was seen, retention sutures were associated with a significantly increased rate of patient morbidity, primarily discomfort. Alternatively, a recent RCT by Khorgami et al. (2013) randomized 300 patients undergoing midline laparotomy who were deemed to be high risk for wound dehiscence to fascial closure with and without retention sutures. In these patients, they found a significantly greater rate of wound dehiscence in patients undergoing fascial closure without retention sutures as compared with those who also had retention sutures placed (13.3% vs. 4%, $P = 0.007$). However, the rates of evisceration (2.7% vs. 0.7%, $P = 0.371$), wound infection, and incisional hernia did not differ between the groups (Khorgami et al., 2013). Given the mixed study results and potential for patient morbidity, recent surgical trends suggest a movement away from the routine use of retention sutures and reserving the technique for patients at high risk of fascial dehiscence.

Wound Dressing

Sterile dressings protect surgical wounds from infection and abrasion from clothing and the environment. In addition, they collect blood and fluid that drain from the wound and provide a more socially acceptable cosmetic appearance of the surgical wound for the patient. Typically, Steri-Strips are placed over an abdominal wound to provide extra tensile strength to the suture line. Alternatively, skin glue may be applied to small incisions to protect and reinforce the wound. Certain dressing supplies that contain antimicrobial properties, such as Xeroform, may be used to further protect the incision from infection. Dressings are typically removed within 24 to 48 hours to inspect the wound and redress if necessary.

Perhaps the most important recent advancement in wound closure has been development of negative-pressure wound vacuum-assisted closure (VAC) systems. There are three separate types of wound VAC systems intended to aid in closure of three types of wounds, and each has the potential to provide distinct advantages over wound healing without the aid of a VAC device.

Standard wound VAC systems were developed to aid in the closure of complex surgical wounds. **As opposed to primary closure of a grossly infected wound, placement of a foam pad into the wound and providing negative pressure allow for several important benefits that aid in wound closure: passive wound debridement, active fluid removal from the wound, and**

protection from environmental factors. Proposed secondary effects include increased cell proliferation, improved formation of granulation tissue, and reduced inflammation (Orgill and Bayer, 2013). Standard wound VAC systems have been increasingly used in the treatment of Fournier's gangrene.

Open abdomen wound VAC systems (Abthera) allow for temporary abdominal wall closure with a wound VAC when primary closure is otherwise not possible or is impractical. Used in critically ill patients with an open abdomen, this allows a sterile wound VAC to be placed in the wound, protecting the open abdomen from the environment and removing excess fluid as well. **Use of a wound VAC in the open abdomen has been shown to improve rates of eventual fascial closure and decrease mortality (Bruhin et al., 2014; Cheatham et al., 2013).**

Closed-incision negative-pressure wound VAC systems have also recently gained popularity. These systems are typically battery-powered disposable devices that are placed directly over a closed incision. They can be left in place for up to 1 week postoperatively and have been shown in numerous studies to reduce the risk of SSIs, decrease the rate of seroma formation, and increase blood flow to the surgical incision (Blackham et al., 2013; Bonds et al., 2013; Pachowsky et al., 2012; Semsarzadeh et al., 2015).

Key Points

- Proper attention to the operating room and patient environment can decrease the rate of intraoperative preventable complications.
- Perioperative hypothermia of even 1°C to 2°C is associated with increased estimated blood loss and increased risk of SSI.
- Current guidelines advocate restriction of blood product transfusion for hematocrit greater than 21% in most patients unless there are specific cardiopulmonary risk factors.
- Understanding the mechanisms of dry matrix and biologically active hemostatic agents ensures the appropriate application to augment surgical hemostasis.
- Current literature suggests that closure with continuous, slowly absorbing suture results in the lowest risk of incisional-related complication.

Lower Urinary Tract Catheterization

Joseph M. Jacob MD, MCR, Chandru P. Sundaram MD, FACS, FRCS (Eng)

History

The earliest known record of catheterization is from 1500 BCE. Ancient Egyptians recorded the use of transurethral bronze tubes, reeds, straws, and curled up palm trees. There are references in the writings of Hippocrates (400 BCE) to the use of malleable lead tubes used for catheterization. An S-shaped silver tube used for the treatment of urinary retention was found in the ruins of Pompeii (CE 79) (Feneley et al., 2015). A fourth-century Byzantine medical anthology includes several indications for catheterization of bladder, including fistula repair surgery, urinary retention, and kidney “inflammation.” In the fifth century, Latin authors mention catheter placement in paralyzed patients (Moog et al., 2005). Catheter use was recorded in the middle ages in Spain as well as China. In the 16th century, the use of an indwelling wax and cloth catheter was documented. Benjamin Franklin used a silver wire catheter to treat his brother's urinary retention from a bladder calculus. He later used this catheter on himself when he developed a bladder calculus. In our opinion, one of the most important advances in catheterization was Jean Francois Reybard's invention of the self-retaining catheter in 1855. He developed a catheter with two channels, one for urine drainage and the other to inflate a balloon. In 1929 Dr. Frederic Foley developed the modern balloon-based rubber catheter with an inflatable rubber balloon. This catheter was originally designed for postprostatectomy hemostasis, but soon after production, its use was widely applied. Silicone catheters were developed in 1968, which reduced urethritis, encrustation, and infection (Feneley et al., 2015). Not unexpectedly, the simple concept of lower urinary drainage via catheterization has withstood the test of time and has remained an invaluable aspect of urologic care.

Anatomic Considerations

Male Urethra

The male urethra is about 18 to 20 cm long. The anterior urethra, which is surrounded by the corpus spongiosum, is approximately 16 cm and lies within the penis distally and the perineum proximally. The anterior urethra can be further subdivided into the pendulous or penile urethra; the bulbar urethra, which is surrounded by the bulbospongiosus muscle; and the fossa navicularis. The posterior urethra is 4 cm long and lies within the pelvis proximal to the corpus spongiosum. It can be further subdivided into the preprostatic or bladder neck, prostatic, and membranous urethra (Standring, 2015). The average normal male meatus should accommodate a 24-Fr instrument or catheter. The prostatic urethra should accommodate a 32-Fr instrument and the bladder neck a 28-Fr catheter or instrument (Davis, 1918; Kohler et al., 2008).

Female Urethra

The female urethra is approximately 4 cm in length and is present within the anterior vagina (Standring, 2015). The normal caliber of a female urethra is 22 Fr (Uehling, 1978).

Indications for Lower Urinary Tract Drainage

Diagnostic

There are multiple diagnostic indications for lower urinary tract drainage. Patients, especially children or females, may require catheterization of the urinary bladder for sterile acquisition of urine for culture. This can be important in cases in which there is a suspicion for contamination of the urine with clean-catch specimens. Often, when patients are admitted to the hospital for varying diagnoses such as acute kidney injury or sepsis, catheterization is indicated for urine output monitoring. When lower urinary tract trauma is expected, catheterization may be required for diagnosis of a urethral or bladder injury. A cystogram requires the insertion of a catheter into the bladder, whereas a retrograde urethrogram requires insertion of the catheter into the fossa navicularis. Flexible and rigid cystoscopy are a form of lower urinary catheterization and are used to diagnose various lower urinary tract pathologies. The performance of urodynamics studies requires catheterization of the bladder to measure postvoid residual, to fill the bladder during measurement, and to insert the sensor catheter to measure detrusor pressure. Finally, catheterization may be required to collect cytology when there is a suspicion of urothelial cancer.

Therapeutic

Lower urinary catheterization has remained an essential part of urologic therapy. Urinary catheterization for urinary retention is a simple yet extremely important urologic treatment. Many causes of urinary retention including benign prostatic hyperplasia (BPH), clot retention, and urethral strictures can be temporarily treated with catheterization. In these situations, catheterization allows the urologist to temporize the emergent situation and permits the clinician to offer definitive therapy in a planned and controlled environment. Long-term urethral catheterization is used for selected patients with urinary retention and urinary incontinence when other definitive treatment options are not possible. It may also be indicated in the setting of hematuria if continuous bladder irrigation is required. Intravesical treatments such as Bacillus Calmette-Guérin vaccine or mitomycin for bladder cancer or dimethyl sulfoxide for interstitial cystitis necessitate the catheterization of the bladder. Catheterization or dilation of the urethra can be used to treat urethral strictures. Lower urinary tract catheterization is also performed during major surgery to drain the bladder and monitor urine output. Extraperitoneal bladder injury and selected cases of intraperitoneal bladder injury are managed with urethral catheterization. Small vesicovaginal fistulas can also be managed conservatively with urethral catheterization.

Contraindications

The only absolute contraindication to urethral catheterization is a suspected or confirmed urethral injury or a history of bladder neck closure or repair. Relative contraindications include recent urethral surgery or urethral stricture (Thomsen and Setnik, 2006). Urethral catheterization should not be placed in a patient with an artificial urinary sphincter (AUS) without the consultation of a urologist. The technique for catheter placement in patients with an AUS is described later in this chapter.

Technique of Urethral Catheterization

Preparation for Catheterization

Before placement of any type of lower urinary catheter, the clinician must prepare all the necessary supplies. These supplies vary based on the situation; however, in most cases, all the required supplies will be packaged in a catheter kit or tray. These trays usually include sterile gloves, a catheter, sterile lubricant, antiseptic solution, sterile drapes, sterile water, and a collection bag with tubing (Thomsen and Setnik, 2006). Based on the indication for catheterization, the clinician must decide whether more supplies or special catheters are needed. Before catheterization, the catheter tray or supplies should be opened sterilely and sterile gloves should be placed. The catheter balloon should be tested by inflating and deflating it with sterile water, and the antiseptic solution placed on cotton balls or swabs. The sterile field should be established with sterile drapes, and the external genitalia should be properly prepared with antibacterial solution.

Urethral Catheterization in Men

The male patient should be in a supine position. If the penis is uncircumcised, the foreskin should be retracted and the glans should be sterilized. Ten to fifteen mL of sterile lubricant are slowly injected directly into the meatus, then the distal glans is pinched to prevent the reflux of lubricant from the meatus. At this point, the nondominant hand is considered not sterile and the remainder of the procedure should be performed with the other hand. The catheter is gently inserted into the meatus while the penis is pulled straight and taut. It is not uncommon to feel slight resistance at the urinary sphincter or prostate. Slow, steady pressure is continued until the catheter is completely positioned and the balloon port is at the level of the meatus**. It is essential that the catheter be inserted completely before filling the balloon, even though the return of urine may be seen before this.** Some urine return may be encountered before passing the catheter passed the bladder neck. Then the balloon is filled with sterile water and the catheter pulled distally to ensure proper placement. The balloon should not be inflated until flow of urine through the catheter is confirmed. If it appears that the catheter is beyond the bladder neck and there is no return of urine, the catheter may be obstructed by the lubrication. In this case, the catheter is irrigated with sterile water or saline. If the foreskin was retracted, the clinician must ensure that the foreskin is replaced over the glans to prevent paraphimosis (Thomsen and Setnik, 2006). Sterile 2% lidocaine jelly may be used instead of lubricant jelly in patients who are apprehensive or if initial attempts at catheterization have failed.

Urethral Catheterization in Women

In most circumstances, catheterization of the female urethra should be less difficult than catheterization in the male. The patient should be in a supine frog-legged position. The thumb, pointer, and middle finger of the nondominant hand are used to spread the labia before sterilization of the meatus. Lifting anteriorly while spreading the labia may help improve visualization. The catheter is lubricated with sterile lubricant, then the catheter is inserted gently into the meatus. Very little or no resistance should be encountered. Once urine return is noticed, the balloon port is filled with sterile water. If visualization of the meatus is difficult, the patient may be placed in Trendelenburg position, and more assistance may be needed for retraction (Manzano and Lacroix, 2014).

Urethral Catheterization of Children

Catheterization of the urethra in a male and female child should follow the same principles as discussed earlier. However, there are a few important considerations when catheterizing the lower urinary tract of a child. Male children may have physiologic phimosis, which should not be forced to retract (Lacroix et al., 2010). In this circumstance, the foreskin can be gently moved ventrally or dorsally to identify the meatus. Male children may exhibit an intense urinary sphincter contraction in response to manipulation of the urethra. In this case, steady pressure is held at the sphincter without forcing until the resistance is released. Usually resistance abates once the child takes a deep breath. Clinicians should also ensure that the catheter size is appropriate for the age of the child (Table 11.1).

TABLE 11.1

Recommended Size of Pediatric Catheters According to Age

TYPE OF CATHETER	AGE OF CHILD					
	NEWBORN	**1–11 MO**	**12–23 MO**	**2–6 YR**	**7–12 YR**	**>12 YR**
Straight—French gauge	4.0–6.0	6.0–8.0	8.0	10.0	10.0–12.0	14.0
Balloon—French gauge	6.0	6.0–8.0	8.0	8.0–10.0	12.0–14.0	14.0–16.0

Types of Urethral Catheters

Urethral catheters can vary by size, shape, number of ports, and material. Catheters either have a straight tip or a coudé tip. A council tip catheter can be passed over a wire because it has an opening at the distal tip, unlike a typical catheter, which is blind-ending. Council catheters are available with either a straight or coudé tip. Catheters are available with either one, two, or three ports. A one-port catheter can be effective in drainage of the bladder because its lumen is greatest in diameter. However, a one-port catheter cannot be anchored because of lack of a balloon port. A two-port catheter is the most common type and is effective for anchoring because a balloon can be filled with sterile water to prevent the catheter from migrating distally. A three-port catheter is used for bladder irrigation, most commonly in patients with hematuria. The extra port is usually connected to a saline bag and fluid is continuously infused. Many types of materials and coatings are used for different types of catheters. Catheters can be manufactured from latex, rubber, silicone, or polyvinylchloride (PVC). They can be manufactured with hydrophilic, antibiotic, or antiseptic coatings.

Numerous studies have been performed attempting to compare patient outcomes based on catheter material or coating. Three trials compared standard catheters with silver oxide impregnated catheters. Pooling these trials together still does not provide enough evidence to recommend silver oxide catheters over the standard. Several trials comparing silver alloy catheters to the standard did show a significant decrease in asymptomatic bacteriuria defined as greater than 10^5 colony-forming units (Schumm and Lam, 2008). However, when using symptomatic urinary tract infections (UTIs) as the primary endpoint, no difference was found (Pickard et al., 2012). A small trial compared minocycline- and rifampicin-impregnated with the standard catheter in men after prostatectomy. The risk of asymptomatic bacteriuria was decreased; however, there was no significant difference in symptomatic bacteriuria (Darouiche et al., 1999). No difference in asymptomatic bacteriuria was found in multiple trials comparing different types of standard catheters, including silicone, latex, hydrophilic polymer-coated latex, and PVC catheters (Chene et al., 1990; Nickel et al., 1989; Tidd et al., 1976). One trial showed that silicone catheters had a lower incidence of reported urethral symptoms compared with nonsilicone catheters (Kalambaheti, 1965), and another showed a decrease in urethritis diagnosed on urethral swab when comparing silicone with latex (Nacey et al., 1985).

Catheter Sizing

The clinician should first determine the indication for catheterization and understand the anatomy of the patient's urethra based on age and history. Based on these factors, the clinician should then choose the most appropriate catheter for the specific patient. For example, a 30-year-old man with spinal cord injury likely requires a different size catheter than a 75-year-old man with urinary retention. This is discussed later. Also, some patients may have a latex allergy, and therefore a silicone or PVC catheter should be used. French (Fr) is the accepted measurement unit for urinary catheters along with other types of catheters such as coronary catheters. **To convert French to millimeters, the number in French is divided by 3. As the French size increases, the diameter of the catheter lumen increases** (Table 11.2). **The sizing units describe the diameter of the lumen.**

[a] These are approximate measurements.

Double-Lumen Catheters

Double-lumen catheters are likely the most prevalent and are used commonly for simple catheterization of patients in the hospital setting. Intraoperatively, anchoring a catheter may be necessary, and usually double-lumen catheters are used with a temperature-sensing probe built into the lumen. This aids the anesthesiologist to monitor the temperature of the patient intraoperatively. Double-lumen catheters may be made with latex, silicone, or PVC. They also may have a straight tip or a coudé tip.

Single-Lumen Catheters

Single-lumen catheters are usually indicated in patients who require intermittent catheterization. This can be in the setting of urethral catheterization in patients with a catheterizable channel. Typically, a catheterizable channel can accommodate a 12- or 14-Fr catheter. As the diameter increases, usually the rigidity of the catheter increases. **Catheter type or material also influences rigidity.** Red rubber catheters are soft and are less likely to create a false passage. However, they may not be rigid enough to traverse an obstructing prostate or a valve mechanism such as in an ileocecal valve in an Indiana pouch or a valve created at the anastomosis between the orthotopic bladder and a catheterizable channel.

Hematuria Catheter

A hematuria catheter can be extremely helpful in patients with significant hematuria with clots. These catheters usually have three lumens to initiate continuous bladder irrigation. They are also made with PVC, which does not compress. Alternatively they are made of latex along with a metal spring, which prevents the catheter from compressing. This allows the clinician to irrigate without the lumen of the catheter narrowing as negative pressure from a syringe is used to remove clots. These catheters also usually have a large drainage eye at the tip, which aids the extraction of thick material (Fig. 11.1).

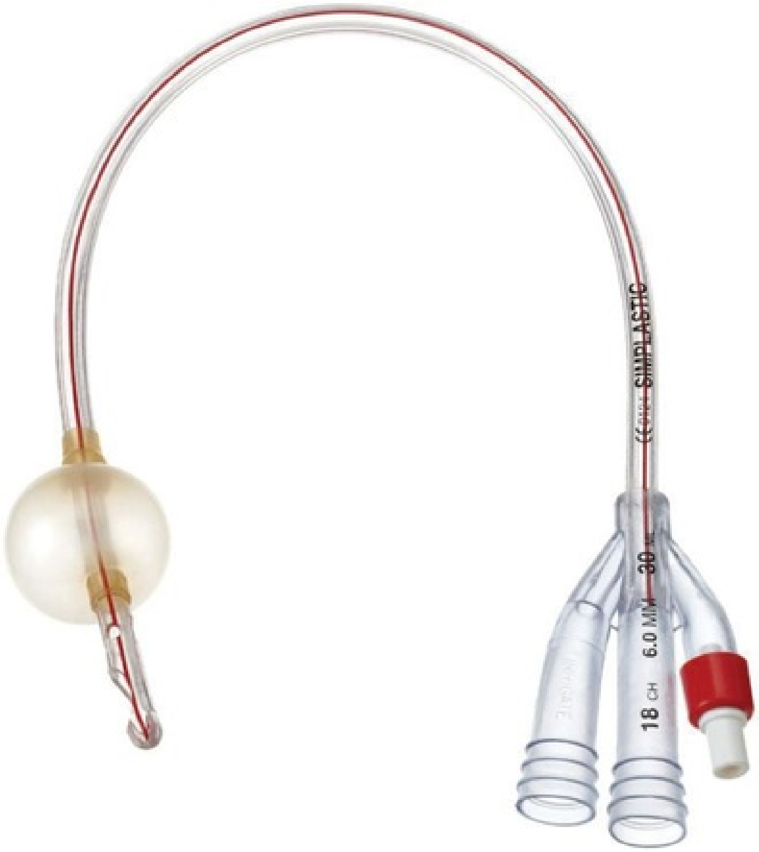

FIG. 11.1 Three-way hematuria catheter. (**Image courtesy of Teleflex Incorporated. © 2019 Teleflex Incorporated.** All rights reserved.)

Another type of hematuria catheter is a four-lumen catheter. One lumen is for the balloon, one for continuous flow, one for drainage, and the fourth for simultaneous irrigation when needed (Fig. 11.2).

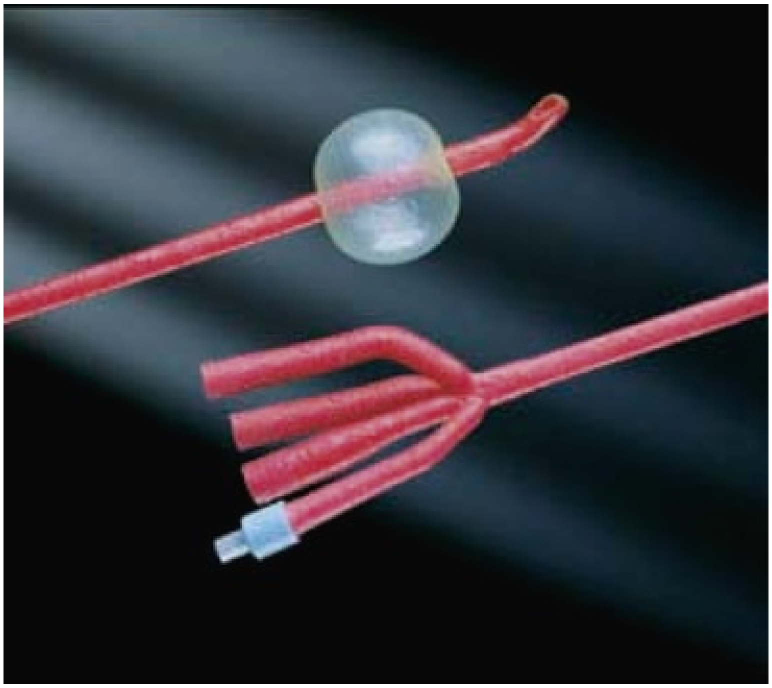

FIG. 11.2 Four-way catheter. (From https://www.crbard.com/medical/en-US/Products/4-Way-Infection-Control-Specialty-Foley-Catheters.)

Diagnostic Catheters

The Lapides Diagnostic Foley catheter has five radiopaque rings, each 1 cm apart for calibration of female urethra length. The Davis and Trattner Diagnostic Foley catheters were used to diagnose urethral diverticula in females. These catheters have two balloons, one for the bladder neck and one to seal the meatus so that contrast can be instilled in the urethra. Currently, MRI technology has likely replaced the diagnostic method using these specialty catheters (Fig. 11.3).

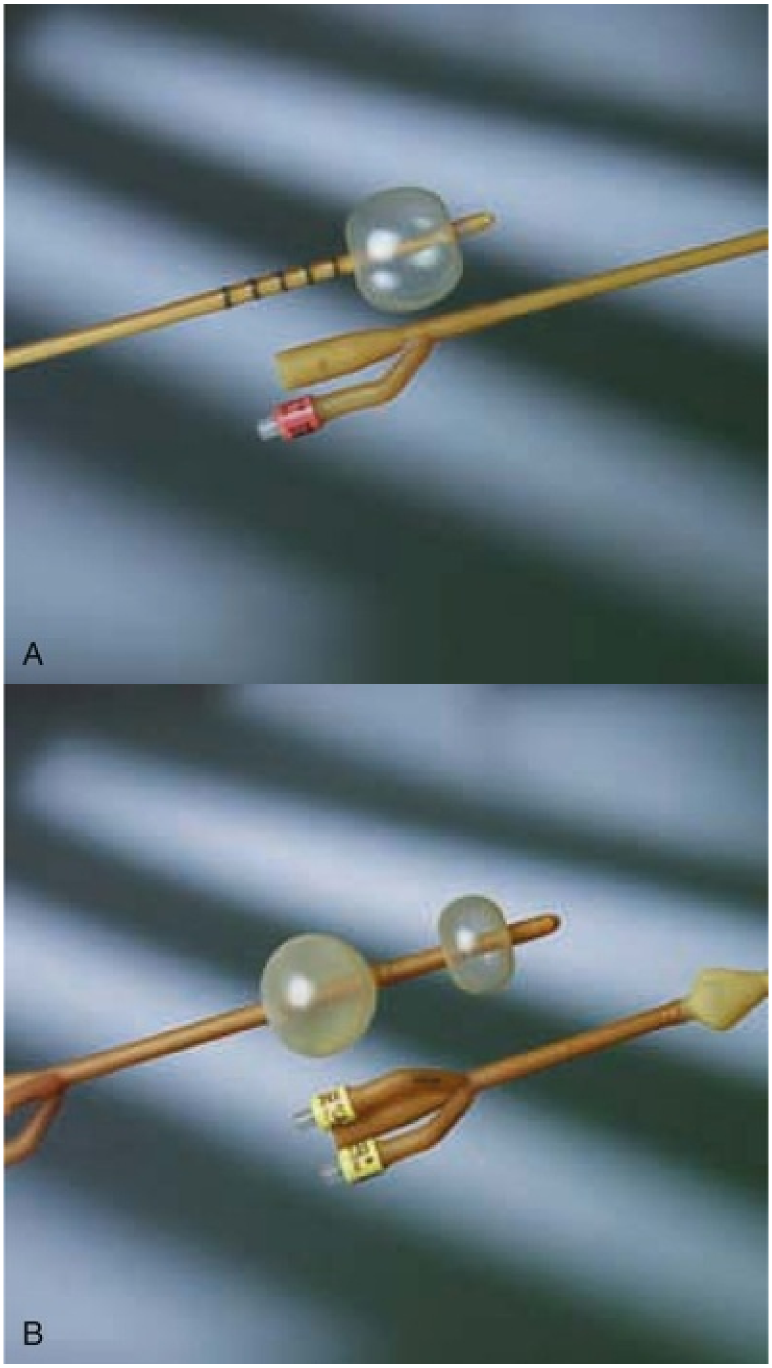

FIG. 11.3 Diagnostic catheters. (A) Lapides diagnostic catheter. (B) Davis and Trattner diagnostic catheters. (From https://www.crbard.com/medical/en-US/Products/Diagnostic-Foley-Catheters.)

Urodynamic catheters are essential for diagnoses of many different bladder pathologies. The catheter has three ports, one is a pressure sensor, one is for filling, and the other is a balloon port.

Drain Catheters

Malecot catheters are used primarily postsurgically for optimal drainage. There is no balloon port, but instead the tip has four small arms that can be compressed for insertion but hold the catheter in place (Fig. 11.4). These can be used as nephrostomy tubes or suprapubic (SP) tubes after a simple prostatectomy or are commonly placed intraoperatively during Indiana pouch creation. A Pezzer tube is similar with a slightly different configuration (Fig. 11.5).

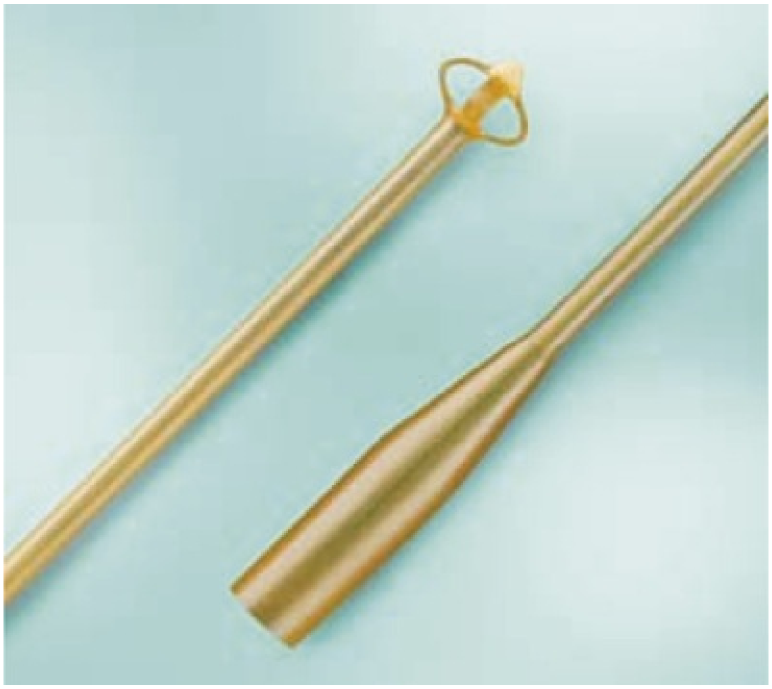

FIG. 11.4 Malecot tube. (From https://www.crbard.com/medical/en-US/Products/Malecots.)

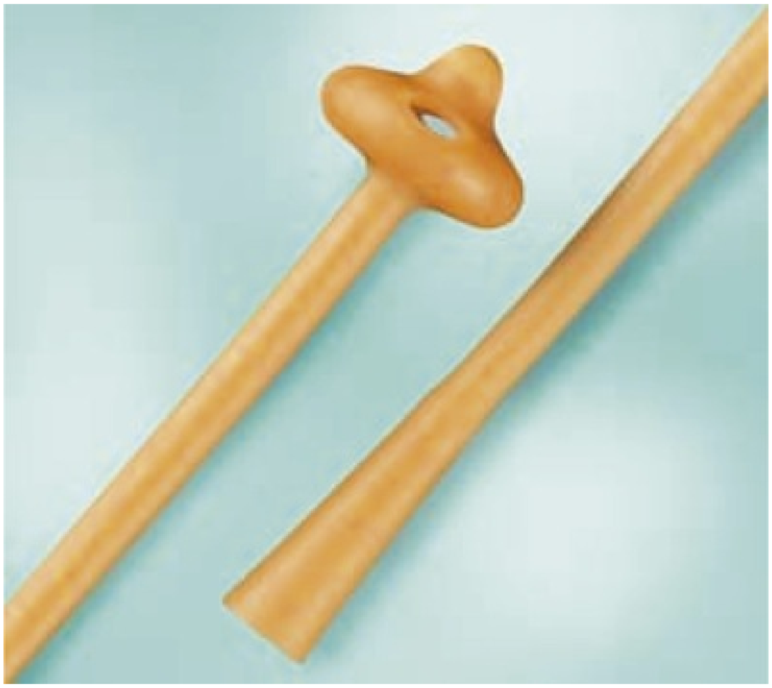

FIG. 11.5 Pezzer tube. (From https://www.crbard.com/medical/en-US/Products/Pezzers.)

Condom Catheters

Condom catheters are a type of external urinary drainage. They are typically used for male patients who have mobility issues with no concern for bladder outlet obstruction (Fig. 11.6).

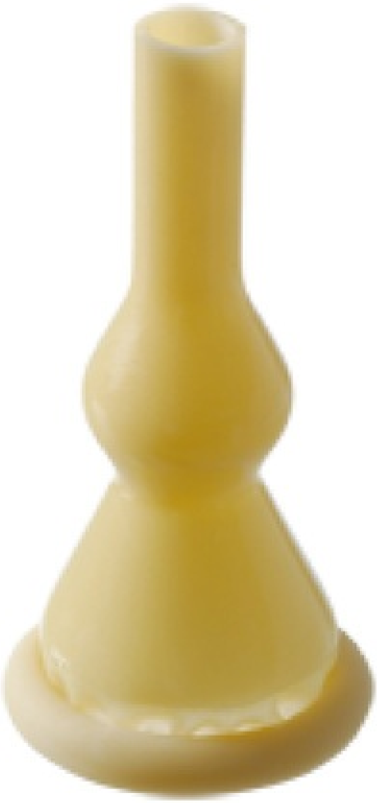

FIG. 11.6 Condom catheter. (From https://www.coloplast.us/freedom-cath-en-us.aspx#.)

Key Points: Catheters

- There are many indications for urethral catheterization and many sizes and types of catheters that can be used.
- As the French size increases, the diameter of the catheter lumen increases (see Table 11.2).
- Catheter rigidity varies by material.
- Three-way hematuria catheters should be used if clot retention is suspect.

Suprapubic Catheterization

Indications

SP catheterization is indicated in many situations and may even be necessary in situations in which the urethra is inaccessible. Patients with a urethral disruption from trauma may require temporary placement of an SP catheter for bladder drainage. This access may then be used to fill the bladder with contrast and perform a voiding urethrogram to aid in visualization of the proximal urethra. Patients may also have a urethral stricture or multiple strictures that are too dense to dilate without general anesthesia. Recent urethral or bladder neck reconstruction may also preclude the use of a urethral catheter. SP catheterization can be an invaluable procedure in scenarios such as these especially when the patient urgently requires bladder drainage.

In patients requiring long-term catheterization, an SP tube may be more comfortable and has the potential to avoid certain complications such as urethral erosion or stricture. Although long-term catheterization is not recommended, some patients may require it. For example, there are patients that may be too unhealthy to undergo major urologic procedures such as simple prostatectomy, urinary diversion, bladder augmentation, urethroplasty, or even transurethral resection of the prostate. If these patients have significant retention or urinary incontinence, SP catheterization may be considered.

Techniques

There are various techniques to place an SP catheter, which include open cystotomy, trocar technique, Seldinger technique, and Seldinger technique with ultrasound guidance. Occasionally, SP drainage is indicated without placement of a catheter. In this case, once the bladder is palpated, a 21-gauge needle can be inserted and urine can be aspirated. This can be done under ultrasound guidance if the bladder is not easily palpated, such as in an obese person or if there is a history of prior abdominal or pelvic surgery. **The needle should be placed in a vertical plane 1 fingerbreadth cephalad to the pubic symphysis** (Harrison et al., 2011). The clinician should aspirate as the needle is inserted in an anterior to posterior direction. Once urine is confirmed, the needle is advanced slightly and the bladder continues to drain.

Open Cystotomy

Open cystotomy can be performed in various ways. Usually this procedure is performed under general anesthesia or sedation. The bladder is distended to capacity. A small incision is made in the skin, and retractors are used to expose the rectus fascia. The fascia is incised and the rectus muscle is spread. Once the bladder is palpated, stay stitches can be placed to lift the bladder toward the incision. A small incision is made in the bladder, and any catheter can be placed and anchored in the bladder. Hemostasis is achieved and the catheter is then secured to the skin with permanent suture. Alternatively, after incising the skin, a trocar, usually stainless steel, can be placed into the bladder under cystoscopic vision. A catheter can then be placed through the outer sheath once the obturator is removed (Fig. 11.7).

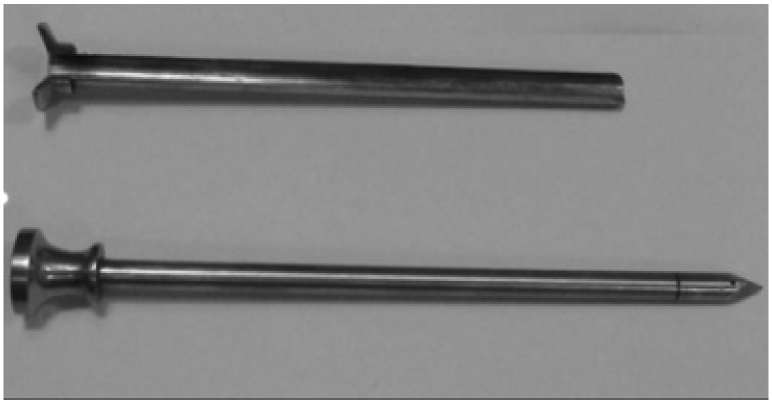

FIG. 11.7 Stainless steel obturator and outer sheath. (From Goyal NK, Goel A, Sankhwar SN: Safe percutaneous suprapubic catheterization. *Ann R Coll Surg Engl* 94:597–600, 2012.)

Another method uses an adapted urethral sound, referred to as the Lowsley retractor. The Lowsley retractor is advanced into the bladder through the urethra. It is then pushed anteriorly toward the abdominal wall. A skin incision is made, and electrocautery is used to cut down onto the tip of the retractor. The retractor is then exposed up into the incision. A catheter is then secured to the retractor usually with a 2-0 silk tie. The Lowsley and catheter are then pulled back through the urethra and out the meatus. The tie is cut and the retractor is released from the catheter. Cystoscopy is used to guide the catheter back proximally into the urethra and safely in the bladder. The balloon port is then filled and the catheter secured to the SP skin with permanent suture (Edokpolo and Foster, 2011; Zeidman et al., 1988).

Placement With a Guidewire and the Seldinger Technique

These techniques are most commonly used under local anesthesia. Usually the skin and the future SP tract are injected with lidocaine after the skin is prepped. The site of puncture is usually 2 to 4 cm cephalad to the pubic symphysis. A small incision is made in the skin, and a 21-gauge needle is advanced in a vertical direction similar to aspiration described earlier. This can be performed under ultrasound guidance to ensure the bladder is distended and the tract is free of bowel. If the bladder is not distended, the clinician should either fill the bladder or wait until the bladder is eventually distended. The ultrasound probe can be placed transversely, and the probe should be angled slightly toward the needle. The needle is then advanced until urine is returned. Advance the needle slightly further posterior and then place a super stiff guidewire into the bladder. Once the needle is removed, various kits are available to advance a catheter over the wire. Some kits include a peel-away sheath that can be inserted over a wire. Care must be taken as to not advance the catheter too far and into the bladder neck (Jacob et al., 2012; Martino et al., 2017; Mohammed et al., 2008). The catheter is then secured by filling the balloon or deploying the pigtail. The clinician can also place a council tip catheter over a wire after dilation or after incising the fascia.

Difficult Catheterization

Prostatic Obstruction

Likely the most common cause of difficulty with lower urinary tract catheterization is BPH with obstruction. The prostatic adenoma causes a narrowing of the prostatic urethra. The narrowing combined with the angle of the male urethra can lead to the inability to advance the catheter or the unfortunate iatrogenic creation of a false passage posterior to the prostatic urethra. Usually, smaller catheters such as 14 or 16 Fr will not pass through the prostatic urethra. An 18-Fr catheter has more rigidity and the tip has more surface area, which may aide in advancing past the prostatic urethra. **If BPH is suspected, ideally the clinician should use at least an 18-Fr catheter with a coudé tip**. The coudé tip was developed to follow the angle of the male urethra. There is a small raised marker on the end of the coudé catheter that shows the orientation of the tip. The clinician should ensure this mark is always anterior, which will point the coudé tip anteriorly. Usually the combination of a coudé tip and at least an 18-Fr catheter is sufficient to advance a catheter in a man with prostatic obstruction. If a false passage has been created, cystoscopy is indicated to not exacerbate the extent of the false passage. If blood is noticed in the catheter port or at the tip of the catheter once removed after difficulty with passage, a false passage should be suspected. Using cystoscopy allows the clinician to visually traverse a false passage, usually by angling the camera anteriorly, and a guidewire can be placed once the bladder is entered. A council tip catheter may then be used, which is passed over the wire.

Urethral Stricture

Urethral strictures can occur at any position in the urethra. The clinician can estimate the location of the stricture based on the amount of catheter that is passed before feeling resistance. Occasionally, gentle pressure may dilate a soft stricture, and the catheter may pass beyond the stricture. Strictures at the membranous urethra are more likely to lead to a false passage because of the angle of the urethra. However, a false passage may occur anywhere in the urethra. If a stricture is suspected, the clinician may attempt to pass an atraumatic guidewire, which is usually a hydrophilic wire, past the stricture and into the bladder. Most efficiently, a cystoscope is used to pass the wire under direct vision. An atraumatic wire can be exchanged for a more rigid guidewire through a 5-Fr catheter. Urethral dilators can be passed over the wire. Usually dilation is stepwise, starting from a small dilator size and progressively increasing the dilator sizes. Care must be taken not to pass the dilator too far, causing a puncture in the posterior wall of the bladder. Typically, the clinician must dilate one size larger than the catheter because of the decreased rigidity of the catheter compared with the dilator. For example, if a 16-Fr catheter is planned, dilation should be performed until at least 18 Fr. A balloon dilator may be used instead of urethral dilators (Giesy et al., 1984). Alternatively, filiform dilators can be used. In some circumstances, a stricture may be too dense or too long, and dilation may not be possible. Emergently, an SP tube can be placed. If it is not an emergent situation, operative management such as direct vision urethrotomy or urethral reconstruction may be preferred before dilation.

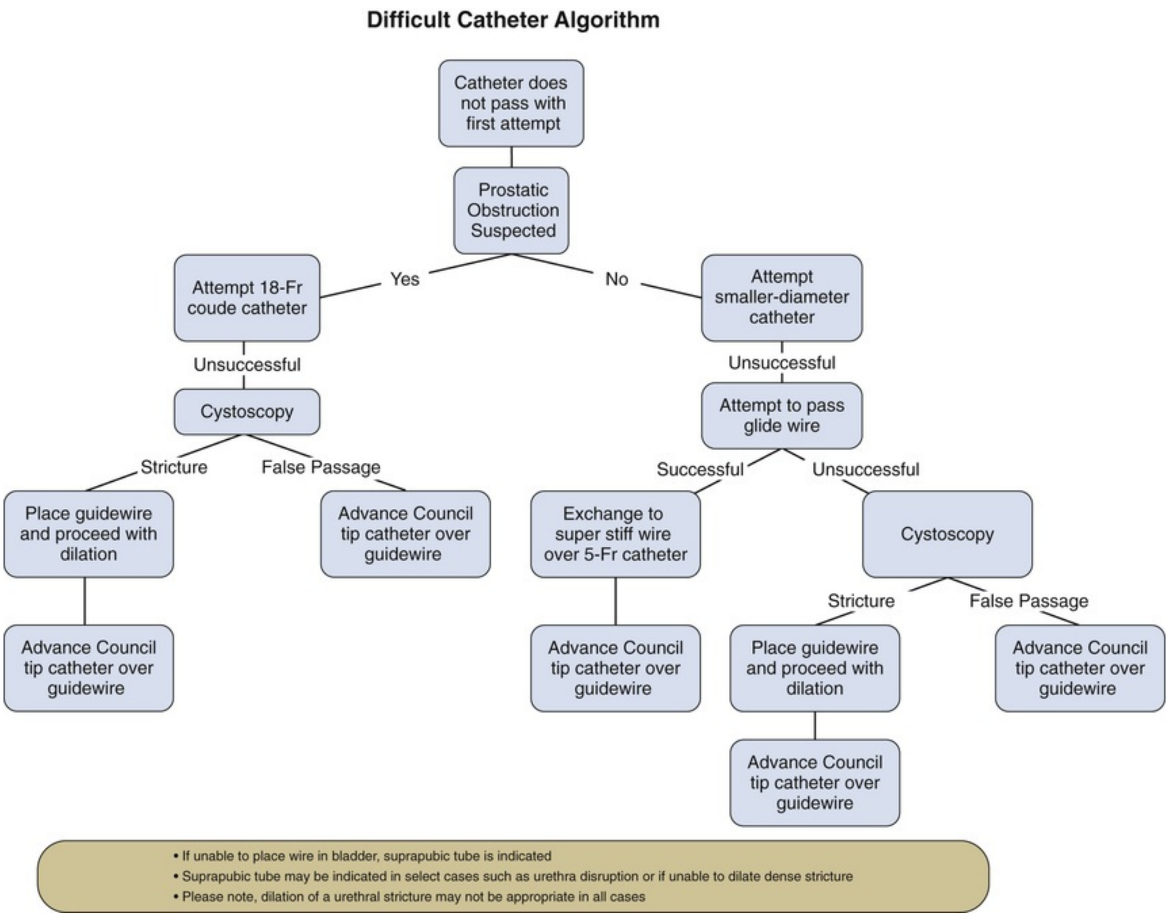
Urethral Trauma

Urethral trauma can lead to partial or complete urethral injuries. **In posterior urethral injuries, one gentle passage of a catheter may be attempted.** If resistance is noticed, the clinician should immediately remove the catheter. Primary endoscopic realignment can be attempted depending on the stability of the patient (Herschorn et al., 1992). An SP catheter may be required. Urethral trauma is discussed in further detail in Chapter 133.

Abnormal Anatomy

Posterior Urethral Valves

Newborn males born with posterior urethral valves may require urgent catheterization. A blunt-tip 5-Fr catheter can be placed in ice and then shaped with an anterior curve to allow the catheter to pass anterior to the valves. Alternatively, one can place the fourth finger in the newborn's rectum and guide the catheter anteriorly past the valves. If a urethral catheter is unsuccessful, ultrasound-guided SP tube placement is required (Fig. 11.8).



Difficult Catheter Algorithm
Catheter does not pass with first attempt
Prostatic Obstruction Suspected
Yes
No
Attempt 18-Fr coude catheter
Attempt smaller-diameter catheter
Unsuccessful
Unsuccessful
Cystoscopy
Attempt to pass glide wire
Stricture
False Passage
Successful
Unsuccessful
Place guidewire and proceed with dilation
Advance Council tip catheter over guidewire
Exchange to super stiff wire over 5-Fr catheter
Cystoscopy
Stricture
False Passage
Advance Council tip catheter over guidewire
Advance Council tip catheter over guidewire
Place guidewire and proceed with dilation
Advance Council tip catheter over guidewire
Advance Council tip catheter over guidewire

- If unable to place wire in bladder, suprapubic tube is indicated
- Suprapubic tube may be indicated in select cases such as urethra disruption or if unable to dilate dense stricture
- Please note, dilation of a urethral stricture may not be appropriate in all cases

FIG. 11.8 Algorithm for difficult catheter placement.

Obesity

Obese patients, especially with a large amount of infrapubic adipose, can present a challenge in catheter placement. In a female, exposure can be attained with the help of others to provide adequate retraction. The bed can be placed in Trendelenburg as well. If the urethra is still difficult to visualize, the clinician can place two fingers in the vagina and pass the catheter while guiding it anteriorly with the fingers. In obese males with a buried penis, usually applying posterior force to the infrapubic area allows the clinician to identify the meatus. Often phimosis is encountered because of the irritation from poor hygiene or urine incontinence. In this case, a dorsal incision in the foreskin may be necessary.

Reconstruction of the Lower Urinary Tract

In patients with a history of urologic surgery, lower urinary catheterization may be extremely difficult or may not be possible. **The clinician should obtain a thorough history and all prior operative records before instrumentation.** If a bladder neck closure has been performed, obviously urethral catheterization should be avoided. Similarly, urethral catheterization in patients with continent or incontinent diversions after cystectomy should not be attempted except in the case of an orthotopic bladder replacement.

Bladder Replacement or Neobladder

A bladder replacement should be easily catheterizable through the urethra as long as there are no anastomotic issues or tumor recurrence. If catheterizing the urethra is unsuccessful, clinicians must take great caution in placing an SP tube. Usually the ileum falls into the pelvis after cystectomy and can easily be injured during SP tube placement. SP tube placement should be performed with ultrasound guidance. If an SP catheter was placed during the cystectomy and creation of the bladder placement, often a scar from the old SP site can be identified on examination. This old tract can be used to guide the placement of a needle because this theoretically was the location that was pulled toward the abdominal wall by the catheter. Most likely the old SP site is scarred and therefore safe from bowel injury. However, caution should still be emphasized. If emergent decompression is required, likely the bladder replacement will be palpable in the pelvis. The old SP site, if present, should be a safe location to insert a needle. The needle should be inserted with a syringe drawn back to identify urine once the bladder replacement is entered. If succus is visualized in the syringe, the clinician should obviously remove the needle and choose a different location. A single puncture with a 21-gauge needle should not cause significant injury to the small bowel. Once access is obtained into the bladder replacement and urine return is visualized, any of the various SP tube techniques described earlier can then be used.

Continent Urinary Reservoir or Indiana Pouch

Postcystectomy patients with a continent urinary reservoir or an Indiana pouch should not be catheterized per urethra except in certain circumstances such as a pelvic abscess that requires drainage. The reservoir is usually placed in the right lower quadrant with a catheterizable channel most commonly in the right lower quadrant. Occasionally, patients are unable to catheterize through the channel for various reasons. **Most commonly, if the reservoir becomes overly distended,**

the channel will kink and will not accommodate the passage of a catheter. Forcing a catheter should not be attempted because of the risk of channel perforation. Also, patients may inadvertently create a false passage in the channel or may be unable to catheterize because of severe stomal stenosis. If a false passage is suspected, the clinician may use a flexible cystoscope or ureteroscope to traverse the false passage and gain access to the reservoir with a guidewire. A council tip catheter can be placed over the wire. Leaving the catheter in place for 1 to 2 weeks is usually sufficient for the channel to heal. If the reservoir is overdistended, the clinician must use a 21-gauge needle to decompress it. If available, ultrasound guidance should be used. If an SP tube was used perioperatively and an SP site scar is identified, the clinician should advance the needle at this location as described earlier. Usually, in this situation, placement of an SP tube is not necessary because once the reservoir is decompressed, the catheter should pass smoothly through the catheterizable channel because the kinking has been released. If stomal stenosis is the issue, likely an office stomal revision will resolve difficulty with catheterization.

Urinary Conduit

Postcystectomy patients with a urinary conduit also should not be catheterized per urethra except for special situations. Occasionally, a urinary conduit may require catheterization. Patients with severe stomal stenosis may need temporary placement of a catheter to keep the stoma open. Catheter placement may also be indicated in situations such as a parastomal hernia causing obstruction, urine extravasation from the conduit, or conduit stenosis. The clinician should place the catheter in the stoma and then beyond the level of the fascia. The balloon can be filled gently. Usually the balloon is not filled completely to theoretically prevent obstruction of the ureters. Alternatively, the clinician can use a permanent stitch to secure the catheter to the stoma.

Bladder Neck Reconstruction or Closure

An absolute contraindication to urethral catheter placement is a history of bladder neck reconstruction or closure. Severe harm can result from urethra catheterization such as urinary incontinence or urinary fistula. Patients with a bladder neck reconstruction in urgent need of catheterization should have an SP tube placed. Patients with a bladder neck closure will have a catheterizable channel that should be catheterized. If there is a false passage in the channel, which is usually created from appendix or ileum, the clinician may use a flexible cystoscope or ureteroscope to find the correct lumen and place a guidewire into the bladder. Catheter placement over the wire should be performed, and the catheter should be secured to the skin and remain in place to allow for healing of the false passage. If this is unsuccessful, then SP catheterization should be performed with great caution.

Artificial Urinary Sphincter

A relative contraindication to urethral catheterization is a history of AUS placement. Clinicians should avoid urethral catheterization in these patients if at all possible. **If catheterization is required, the sphincter should be completely deactivated before placement. After deactivation, a 12-Fr catheter should be placed.** This catheter should be removed as soon as possible to prevent the possibility of urethral erosion.

Key Points

- The urologist should be prepared to attain lower urinary drainage in almost all situations.
- The clinician should closely review the patient's history and prior operative reports before instrumenting the lower urinary tract.
- If BPH is expected, the practitioner should use an 18-Fr coudé catheter for lower urinary tract drainage.
- A history of bladder neck repair or closure is a contraindication to urethral catheterization.
- Catheter placement should be avoided in patients with an AUS. A 12-Fr catheter should be used after deactivation of the sphincter if necessary.

Complications of Lower Urinary Tract Drainage

Infection

UTIs and catheter-associated infections are discussed in great detail in Chapter 55. According to the Centers for Disease Control and Prevention (CDC), **UTIs are the most common type of health care–associated infections. Most health care–associated UTIs are attributable to urinary instrumentation** (see https://www.cdc.gov/infectioncontrol/guidelines/cauti/). Evidence-based guidelines on the prevention and treatment of catheter associated UTI have been published by the CDC and the Infectious Diseases Society of America (Hooten et al., 2010 and https://www.cdc.gov/infectioncontrol/guidelines/cauti/).

Iatrogenic Trauma

Catheterization of the urethra, especially in men, can cause significant trauma to the urethra. A false passage may be created or even significant gross hematuria from the bladder, urethra, or prostate may result. Patients with spinal cord injury were found to have a 13.5% incidence of gross hematuria (Hollingsworth et al., 2013). A single institution during a 7-month period reported an incidence of iatrogenic urethral injuries of 3.2 per 1000 male admissions. Penile bleeding occurred in 86% of males with iatrogenic urethral injury. In this institution, catheter safety training was implemented and a significant decrease in iatrogenic injuries was reported (Kashefi et al., 2008). This shows that urethral injury from catheterization is a preventable complication. In hospitalized patients, approximately 0.3% experience iatrogenic urethral trauma. Iatrogenic trauma may occur during catheter insertion, balloon inflation, or catheter removal if the balloon is not fully deflated. Education is the most important intervention to prevent iatrogenic urethral trauma (Simhan, 2015).

Stricture

The incidence of urethral strictures from catheterization is estimated to be 3.4% (Hollingsworth et al., 2013).

Erosion

Erosion of the urethra causing iatrogenic hypospadias has been described (Andrews et al., 1998).

Malignancy

The incidence of bladder cancer in spinal cord patients with long-term catheterization is estimated to be 1% (Hollingsworth et al., 2013). This is thought to be related to chronic inflammation because up to half of spinal cord patients with bladder cancer in a large series used external catheters (Kalisvaart et al., 2010). There are no clear guidelines on the frequency and timing of surveillance cystoscopy in patients with spinal cord injuries. Some advocate initiating yearly cystoscopy after 8 years with an indwelling catheter (Stonehill et al., 1996). Urologists must use their best judgment based on the available literature. If long-standing chronic bladder inflammation is suspected, surveillance cystoscopy may be indicated. Theoretically this has the potential to diagnose bladder tumors at an earlier stage; however, there are no prospective data to guide us.

Catheter Knotting and Balloon Malfunction

Pushing a catheter in too far in a child or female can result in the rare complication of catheter knotting. This can prevent the balloon mechanism from deflating and can result in extreme difficulty with catheter removal. Occasionally the balloon malfunctions for unknown reasons. Cystoscopy alongside the catheter may be required with use of a cystoscopic needle or syringe to puncture the balloon (Arena et al., 2002; Jallad et al., 2017). The clinician may attempt to cut the balloon port and place the stiff end of a guidewire through the port to attempt to puncture the balloon before cystoscopy. Alternatively, under ultrasound guidance the catheter can be punctured with a spinal needle. If the balloon is successfully punctured, cystoscopy should be considered to be sure all pieces of the balloon are retrieved.

Key Points

- Catheter-associated UTIs are the most common hospital-acquired infection.
- Catheters may lead to trauma, stricture, and erosion.
- Chronic catheterization can lead to bladder inflammation and increase the risk of bladder cancer.

Fundamentals of Upper Urinary Tract Drainage

Casey A. Dauw MD, J. Stuart Wolf Jr., MD, FACS

Percutaneous Renal Access and Drainage

History

Commonly ascribed to Goodwin and colleagues (1955), the first therapeutic percutaneous nephrostomy actually was performed by Thomas Hillier in 1865 (Bloom et al., 1989). Hillier, at the Hospital for Sick Children at Great Ormond Street, repeatedly aspirated the hydronephrotic kidney of a young boy for symptom relief over a 4-year period until his death at 8 years of age. Subsequently there were a few reports of diagnostic percutaneous renal aspirations, but it was not until Goodwin and colleagues published their landmark report in 1955 that therapeutic percutaneous nephrostomy was rediscovered. Even then, the utility of percutaneous access to the upper urinary tract collecting system was limited to drainage of obstructed kidneys until Fernström and Johansson (1976) described the percutaneous removal of renal calculi, termed *percutaneous pyelolithotomy.*

Subsequently, many procedures have been performed via the percutaneous route to the upper urinary tract collecting system including drainage of an obstructed kidney, nephrolithotomy, endopyelotomy, and resection of urothelial tumors. More recently, percutaneous access to portions of the kidney other than the collecting system has been introduced (addressed in Chapter 84). Specific aspects of the procedures performed through the percutaneous access are covered in Chapters 42, 86, and 99.

Indications

Simple Drainage

Percutaneous renal drainage is effective for most, if not all, obstructions including those in intrarenal, ureteropelvic junction, or ureteral locations. Although lower urinary tract obstruction is best treated by bladder drainage via a catheter, secondary supravesical obstruction can be managed by percutaneous nephrostomy tube placement if other measures have failed to provide adequate drainage. An alternative to percutaneous drainage is drainage through a ureteral catheter or stent placed in a retrograde fashion (later in this chapter). The choice of antegrade or retrograde drainage of the upper urinary tract collecting system depends on the indication, the patient's medical condition and anatomy, and preferences of both the patient and physician.

Generally, a retrograde route to drainage is preferred over the antegrade route. This includes most cases of acute and chronic ureteral obstruction without infection (Rosevear et al., 2007). In the setting of upper urinary tract collecting system obstruction complicated by infection, however, drainage is an emergency and in many such cases, percutaneous rather than retrograde drainage may be best (Ng et al., 2002) unless retrograde drainage can be obtained expeditiously and assuredly. Percutaneous nephrostomy tubes and retrograde ureteral stents are generally equivalent in their capacity to resolve fever in patients with upper urinary tract obstruction and fever (Goldsmith et al., 2013; Pearle et al., 1998), but in a given patient circumstances may dictate preference for one access over the other. Retrograde ureteral stent placement often requires regional or general anesthesia, whereas a percutaneous nephrostomy tube can be inserted under local anesthesia; this is an important consideration in an ill patient. Because the percutaneous route has a greater initial success rate than the retrograde one in cases in which the collecting system is dilated, it might be preferred in a patient who needs rapid intervention. This is especially true when the ureteral obstruction is long, severe, or involving the ureteral orifice—which can retrograde access more difficult. Conversely, untreated coagulopathy is a contraindication to percutaneous access, but ureteral stents can be placed safely in an anticoagulated patient. A final consideration is patient preference. Studies using a validated questionnaire in a population of patients after percutaneous nephrolithotomy suggest that a temporary nephrostomy tube, though equivalent to a ureteral stent in terms of effectiveness of renal drainage, may actually be associated with improved health-related quality of life (Jiang et al., 2017; Zhao et al., 2016).

Diagnostic Studies

In rare instances, percutaneous renal access is necessary solely for diagnostic purposes, such as the Whittaker test, which is an invasive but highly accurate study to differentiate obstructive from nonobstructive hydronephrosis (Jaffe and Middleton, 1980). After obtaining percutaneous access into the kidney, the upper urinary tract is perfused at a constant rate and pressures are transduced in the renal pelvis and urinary bladder. The finding of a pressure differential above 12 cm of water across the ureteropelvic junction or ureter indicates urinary obstruction. For a more detailed description of this test, refer to Chapter 89.

Therapeutic Instillations

Percutaneous renal access can be performed to facilitate instillations of chemotherapeutic agents for upper-tract urothelial lesions or agents for chemolysis of renal stones. For a more comprehensive description of these topics, refer to Chapters 43 and 99.

Percutaneous Renal Surgery

Percutaneous renal access facilitates surgery for upper tract calculi, urothelial tumors, obstruction, and calyceal diverticulae and hydrocalyces. For a more comprehensive description of these surgical procedures, refer to Chapters 42, 43, and 99.

Anatomic Considerations

With limited visualization of the kidney and surrounding structures during standard percutaneous entry guided by fluoroscopy or ultrasonography, understanding renal and perirenal anatomy is critical.

Perirenal Anatomy

The kidneys are well-protected, situated in the retroperitoneum, and surrounded by adipose tissue. The mobility of the kidneys is limited by short renal hilar vessels, although nephroptosis can occur, especially in thin women with a paucity of perirenal fat. In such cases, the kidney not only descends but also rotates anteriorly. This can be troublesome during percutaneous punctures with the patient in a prone position.

The kidneys lie adjacent to the vertebral bodies, usually extending from the 11th or 12th thoracic to the 2nd or 3rd lumbar vertebrae (Fig. 12.1). The right kidney is displaced a few centimeters inferior to the left kidney. The longitudinal axis of the kidneys parallels the lateral edges of the psoas muscles, about 30 degrees from vertical, with the lower poles lateral to the upper poles. The kidneys are also tilted 30 degrees off the frontal plane, with the lower poles anterior to the upper poles. Finally, the kidneys are rotated out of the frontal plane as well, with the lateral aspect of the kidney posterior to the medial aspect, such that each kidney is rotated 30 degrees posteriorly from the renal hilum. This brings the upper pole calyces medial and superficial (dorsal) in relation to the lower pole calyces, which can have important implications for successful renal access.

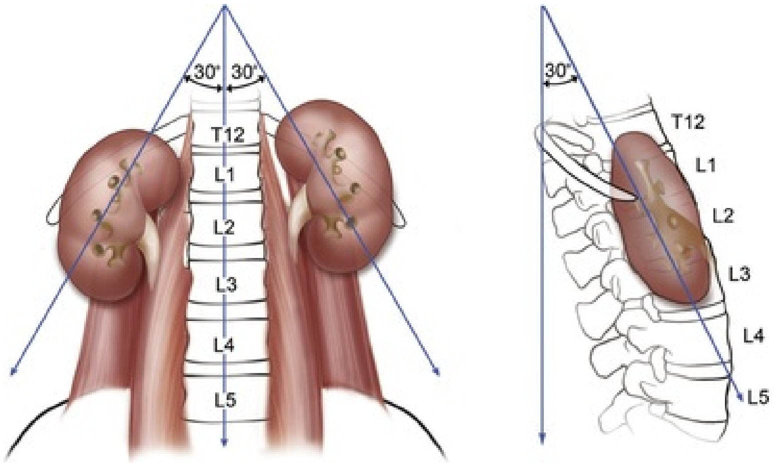

FIG. 12.1 Location of kidneys in the retroperitoneum.

Immediately posterior to the kidneys are the quadratus lumborum and psoas muscles, except at the upper poles where the diaphragm is posterior (Fig. 12.2). **The pleura can be violated during percutaneous entry into the upper pole of the kidney. This risk is greater with more cephalad access.** The lung is above the 11th rib, so direct lung injury is unlikely unless the 10th intercostal space (superior to the 11th rib) is used as the entry site. The ribs curve inferiorly from medial to lateral, such that more portions of the kidney can be approached subcostally with a medial as opposed to a lateral access site.

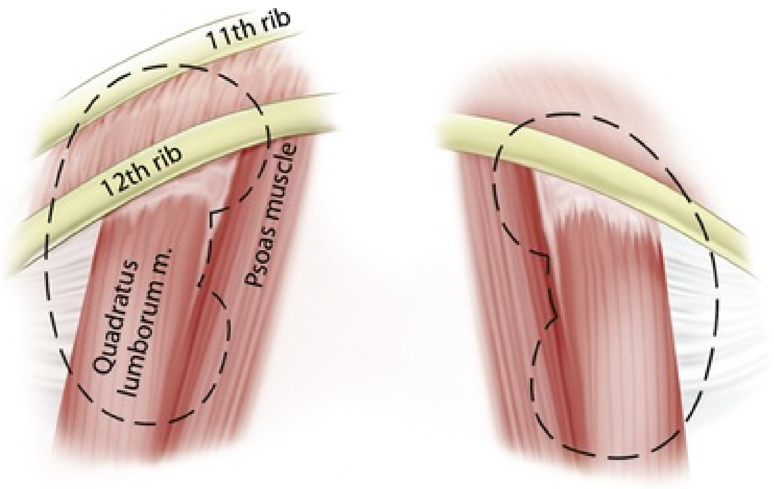

FIG. 12.2 Muscles and ribs posterior to the kidneys.

The lateral, anterior, and medial perirenal relationships are more varied than the posterior ones (Fig. 12.3). On the right side, the liver is anterior to the upper pole of the kidney and can extend in some individuals to cover the entire anterior surface. On the left, the spleen covers less of the kidney anteriorly. Both the liver and spleen can extend lateral to the kidneys and are therefore at risk for injury with a lateral puncture into the kidney. This is especially true in situations in which the liver or spleen are enlarged because of other medical conditions. **The ascending and descending colon can be lateral or even posterior to the right and left kidneys, respectively. The apposition of the colon to the kidney varies with location; it is greatest on the left side and at the lower pole.** In one CT-based study, the left colon was posterior in 16.1% of cases, and the right colon was posterior in 9% of cases at the level of the lower pole. At the mid-portion of the kidney, the colon was posterior in 5.2% and 2.8%, respectively, and at the upper pole 1.1% and 0.4%, respectively (Boon et al., 2001). The relationship of the kidney and the colon vary not only by cranial-caudal location and laterality but also by patient positioning. In a study of 75 patients undergoing CT for non-neurologic indications, retrorenal colon was identified in 2% of patients in the supine position versus 6.8% of patients in the prone position (Sharma et al., 2015). Additional visceral relations to the kidney include the adrenal glands (medial to the upper pole of both kidneys), the duodenum and gallbladder (anterior and medial to the right kidney), and the tail of the pancreas (anterior and medial to the left kidney). These structures can be injured with a misdirected or excessively deep puncture.

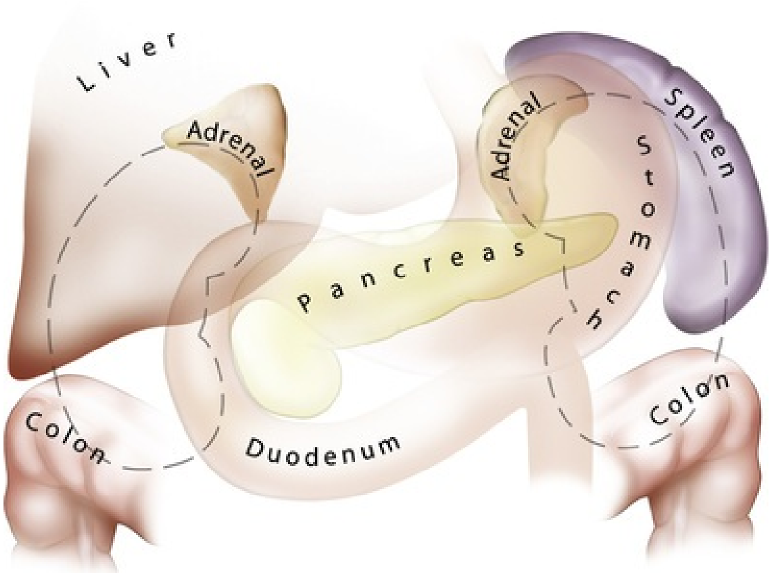

FIG. 12.3 Viscera lateral, anterior, and medial to the kidneys.

Renal Parenchyma and Collecting System

The renal parenchyma is composed of the cortex and the medulla. The cortex, outermost, contains the glomeruli and proximal and distal convoluted tubules. The more interior medulla contains the renal pyramids. These are inverted cones (the base of which is superficial and the apex is deep) that comprise the loops of Henle and the collecting ducts, which coalesce at the apex of the pyramid into papillary ducts that open on the surface of the renal papillae. There are approximately 20 papillary ducts draining into each papilla. The columns of Bertin are invaginations of cortical tissue that surround the renal pyramids except at their apices.

The renal papillae drain into the minor calyces, which are the most peripheral portions of the intrarenal collecting system. If only one papilla drains into a minor calyx, it is described as a simple calyx. When there are two or more papillae entering the calyx, it is termed a *compound calyx*. The outermost wall of the calyx, into which the papilla is set, is the calyceal fornix. **There are 5 to 14 minor calyces in each kidney (mean of 8, with 70% of kidneys having 7 to 9 minor calyces)** (Sampaio and Mandarim-de-Lacerda, 1988). **There are three calyceal groups: the upper, middle, and lower. Compound calyces are the rule in the upper calyceal group, are common in the lower calyceal group, and are rare in the middle calyceal group.** The minor calyces, either directly or after coalescing into major calyces, drain by infundibula into the renal pelvis

(Fig. 12.4). Occasionally a minor calyx will open directly into the renal pelvis without an intervening infundibulum.

Ureter

FIG. 12.4 Upper urinary tract collecting system.

The compound calyces of the poles of the kidney are oriented facing their respective poles. The simple calyces usually come in pairs, one facing anteriorly and one facing posteriorly (Fig. 12.5). Drainage of the upper pole into the renal pelvis is by a single midline infundibulum in most kidneys. Drainage from the lower pole is via a single infundibulum in about one half of kidneys and otherwise via a series of paired anterior and posterior calyces. The middle calyces typically are arranged in a series of paired anterior and posterior calyces. In about two thirds of kidneys, there are two major calyceal systems—an upper and lower one—and the middle calyces drain into either or both systems. In the other one third of kidneys, the middle calyceal system is distinct from the upper and lower systems, coalescing either into a middle major calyx before emptying into the renal pelvis or with drainage of the middle minor calyces directly into the renal pelvis through short infundibula.

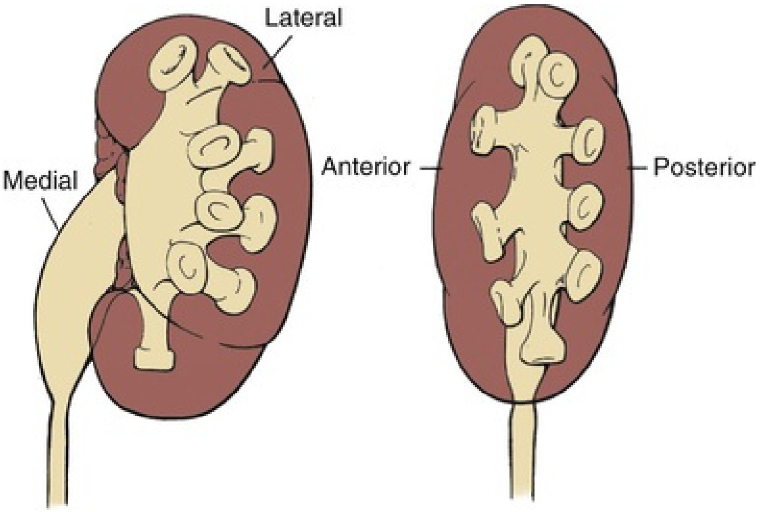

FIG. 12.5 Calyceal orientation of polar and middle calyces. (From Smith AD: *Controversies in endourology.* Philadelphia, 1995, Saunders.)

An important consideration for percutaneous renal surgery is determining the anterior-posterior orientation of the calyces because access (from the typical posterior or posterolateral approach) into a posterior calyx allows relatively straight entry into the rest of the kidney, whereas percutaneous puncture of an anterior calyx requires an acute angulation to enter the renal pelvis, which may not be possible with rigid instrumentation (Fig. 12.6). Efforts have been made to determine which calyces are likely to be anterior and which are likely to be posterior based on their medial-lateral position on anterior-posterior radiography. The distinction pertains to the middle and lower calyceal system, which contains (in almost all middle systems and approximately one half of the lower system) paired anterior and posterior minor calyces. The upper-pole system, with its almost uniformly compound calyceal system, is less problematic in this regard. Paired anterior and posterior calyces usually enter at about 90 degrees from each other. As such, the relative medial-lateral orientation (on anterior-posterior radiography) is determined by the relationship of this 90-degree unit to the frontal plane of the kidney. In a Brödel-type kidney, this unit is rotated anteriorly, such that the posterior calyces are about 20 degrees behind the frontal plane and the anterior calyces are 70 degrees in front of the frontal plane. The posterior calyces are lateral, and the anterior calyces are medial in this case. The Hodson-type kidney is the opposite; the calyceal pairs are rotated posteriorly, with the posterior calyces 70 degrees behind the frontal plane and appearing medial and the anterior calyces 20 degrees in front of the frontal plane and appearing lateral (see Fig. 12.6). Most right kidneys have a Brödel-type orientation (posterior calyces are lateral), and most left kidneys have a Hodson-type orientation (posterior calyces are medial). One group found that, in the lower calyceal system, the medial calyces are anterior and the lateral ones are posterior most of the time (Eisner et al., 2009). **Because variation is considerable, the mediolateral orientation of the calyces on anteroposterior radiography cannot be used to reliably determine the optimal calyx for entry, and additional maneuvers are required to determine the exact calyceal anatomy.** One reliable anatomic distinction is that the upper calyceal group is situated in a mediolateral orientation in 95% of kidneys, in contrast with the anteroposterior orientation of the middle and lower calyceal groups in 100% and 95% of kidneys, respectively (Miller et al., 2013). This means that **most calyces of the upper pole are suitable for percutaneous access from the posterior approach, whereas care must be taken to select a posterior minor calyx in the middle and lower groups.** Within the lower calyceal group, the most inferior calyx is usually anterior, but the next most cephalad calyx is usually posterior.

FIG. 12.6 Relation of anterior and posterior calyces to renal parenchyma in Brödel-type kidney (A) and Hodson-type kidney (B). The optimal site of percutaneous entry from the posterior aspect of the kidney is into a posterior calyx because the path into the renal pelvis is fairly straight. If entry is into an anterior calyx (from the posterior aspect of the kidney), then an acute angulation must be made to enter the renal pelvis, which may not be possible with rigid instrumentation. (From Smith AD: *Controversies in endourology.* Philadelphia, 1995, Saunders.)

Intrarenal Vasculature

Although the renal arterial anatomy is variable, in general the main renal artery divides into an anterior and a posterior branch. The former then divides within or before the renal sinus into four anterior segmental arteries: the apical and lower segmental arteries (which supply the tip of the upper pole and the entire lower pole, respectively) and the upper and middle segmental arteries (which supply the remainder of the anterior half of the kidney). The posterior branch of the renal artery supplies the remainder of the posterior half of the kidney (Fig. 12.7). Once the arteries enter the renal parenchyma, they divide into interlobar (infundibular) arteries. At the cortico-medullary junction, near the base of the renal pyramids, each interlobar artery usually divides into two arcuate arteries that run along the renal pyramid. The next division is into the interlobular arteries, which run along the outer surface of the renal pyramids and are derived at right angles from the arcuate arteries. The final divisions, the afferent arterioles of the glomeruli, come off the interlobular arteries in the peripheral renal cortex. Each renal arteriole is an “end-artery,” meaning that each cell in the kidney derives blood supply from one arteriole. For this reason, renal arterial vascular injury must be avoided to prevent loss of renal function. The potential for arterial injury is least in Brödel's line, an avascular plane approximately at the lateral margin of the kidney, extending from the superior apex of the kidney (limited by the circulation of the apical anterior segmental artery) to the lower pole of the kidney (limited by the circulation of the lower anterior segmental artery). Although anatomically it seems that percutaneous access into the kidney would be safest in a forniceal or papillary location because of avoidance of the interlobar and arcuate arteries, a recent trial refutes this notion. Kallidonis et al. performed a randomized controlled clinical trial of patients undergoing percutaneous nephrolithotomy using either a papillary or infundibular puncture location. There was no difference in hemoglobin change, 30-day complication rate, or length of stay between the two groups (Kallidonis et al., 2017).

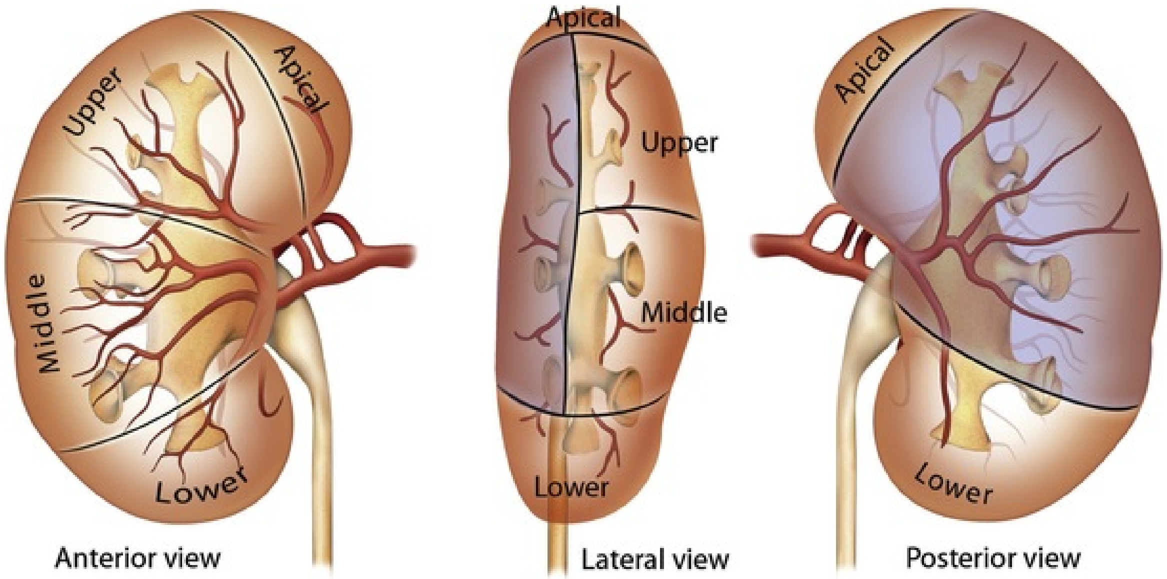

FIG. 12.7 Arterial supply to the kidney. The kidney is supplied by the anterior and posterior branches of the main renal artery. The anterior branch supplies both the anterior half of the kidney and the polar regions via four segmental branches. The posterior branch of the renal artery supplies the posterior aspect of the kidney (represented by the shaded region). An avascular plane, known as the Brödel line, separates the anterior and posterior circulations.

The venous anatomy of the kidney does not have the same defined structure as the arteries. Moreover, there is free cross-circulation among the intrarenal veins via arcades. This enhances vascular outflow from the kidneys, reduces the risk for venous congestion, and makes renal venous injury less damaging to renal function than arterial injury.

Surgical Technique

Provider Obtaining Access

Although some urologists in the United States are trained to obtain percutaneous renal access (Spann et al., 2011), only a minority translate this skill into routine practice (Bird et al., 2003; Lee et al., 2004). Registry data from the United Kingdom indicates that the relative proportion of urologists who obtain percutaneous renal access is higher than that in the United States, but interventional radiologists still obtain access most often (Armitage et al., 2017). **Although rates of successful access and complications differ inconsistently between urologists and interventional radiologists** (El-Assmy et al., 2007; Speed et al., 2017; Tomaszewski, et al., 2010a; Watterson et al., 2006), **it is clear**

that the most vital aspect for a successful procedure is not who performs the puncture, but that the urologist is directly involved in access planning. Ideally, if it is not the urologist who is obtaining renal access, they should be present at the time of percutaneous access to explicitly direct the interventional radiologist as to the appropriate site of puncture for the planned procedure. When access is gained without input of the urologist, the access site is not acceptable for the subsequent percutaneous procedure in a large portion of cases (Tomaszewski et al., 2010a).

Antimicrobial Prophylaxis

Urosepsis is one of the most feared complications after percutaneous access into the renal collecting system. Risk can be mitigated in several ways. Obtain a screening urinalysis, and if there are concerns for infection, then submit for urine culture (Assimos et al., 2016). In patients with risk factors for infection, such as prior history of urinary tract infection, prior history of or current suspicion for struvite stones, anatomic abnormalities (e.g. ureteropelvic junction obstruction or ureteral stricture), or presence of urinary tract reconstruction (e.g. urinary diversion or bladder augmentation), routinely obtain urine culture. Rivera et al. evaluated a large cohort of patients undergoing percutaneous nephrolithotomy and found that only presence of a staghorn calculus was associated with a threefold increase in sepsis (Rivera et al., 2016). The authors suggest that urologists consider a preoperative course of antibiotics in such patients. Special attention should be paid to patients with indwelling foreign bodies such as nephrostomy tubes, ureteral stents, or externalized urinary catheters (suprapubic tube or urethral catheter) as these patients are colonized with bacteria and are at higher risk for postoperative infection. Collecting a urine culture from an externalized drain, though interpretation can be challenging because of potential contamination, is a reasonable practice to tailor preoperative antibiotic choice.

If a preoperative urine culture is positive, treatment with culture-directed antibiotics is imperative. Ideally, a posttreatment urine culture should be obtained to document resolution of bacteriuria, though this is often not practical. For patients with suspected or known struvite stones, those with urinary diversions or reconstructions, and those with externalized drains, it is often impossible to completely eradiate infection and thus the goal should be to suppress bacterial counts before surgery. This can be achieved with culture-directed antibiotics for a duration leading up to any proposed surgical intervention.

The American Urological Association (AUA) recommends periprocedural antimicrobial prophylaxis for all cases of percutaneous renal surgery (Wolf et al., 2008). Although no randomized controlled trials exist to support this recommendation, in a large retrospective but matched case-control study comparing 162 patients with and 162 patients without antimicrobial prophylaxis undergoing percutaneous nephrolithotomy, the rate of fever and other postoperative complications was 3- to 10-fold greater in the group without antimicrobial prophylaxis (Gravas et al., 2012). The need for antimicrobial coverage for simple percutaneous drainage of the upper urinary tract collecting system is not certain.

Antimicrobial coverage should include organisms common to the urinary tract and the skin. Recommended agents include first- and second-generation cephalosporins; aminoglycosides (or aztreonam in patients with renal insufficiency) plus either metronidazole or clindamycin; ampicillin/sulbactam; or a fluoroquinolone. Although there are some series that suggest that administration of antimicrobials for the week before percutaneous nephrolithotomy reduces the risk for infectious complications (Bag et al., 2011; Mariappan et al., 2006), the preponderance of evidence suggests that **when the antimicrobial is being administered only for prophylaxis (i.e., not treatment of known or presumed infection), immediate perioperative treatment for percutaneous nephrolithotomy (24 hours or less) is just as effective as a longer course and is therefore preferred** (Demirtas et al., 2012; Deshmukh et al., 2015; Dogan et al., 2002; Seyrek et al., 2012; Tuzel et al., 2013). A short (≤24 hours) course of antimicrobials at the time of nephrostomy tube removal also can be considered (Wolf et al., 2008).

Management of Anticoagulation

It is important to perform a detailed appraisal of medications that a patient is taking before undertaking percutaneous renal access. Medications such as nonsteroidal anti-inflammatory drugs (NSAIDs), antiplatelet agents, and anticoagulants, with few exceptions, should be discontinued before planned surgery as follows: aspirin, 1 week; warfarin, 1 week; clopidogrel, 5 days; and NSAIDs, 3 to 5 days. Because novel antiplatelet and anticoagulation drugs are rapidly being developed, and this list is not exhaustive, consult with the prescribing physician or a clinical pharmacist as recommended by the ICUD/AUA review paper on this topic (Culkin et al., 2014). The use of perioperative aspirin deserves special mention. Although patients electively taking aspirin for the purpose of primary prevention of cardiovascular disease without coronary artery disease should be counseled to stop aspirin 7 days before surgery. Those with preexisting heart disease or at high risk for heart disease or cerebrovascular disease can continue this medication safely in the perioperative period. Leavitt et al. retrospectively analyzed a large group of patients undergoing percutaneous nephrolithotomy and found that uninterrupted use of aspirin was not associated with greater blood loss or need for transfusion, even when evaluating a subset of high–cardiovascular risk patients (Leavitt et al., 2014).

Diagnostic Imaging

The type of preoperative imaging performed before percutaneous renal access is often determined by the pathology to be treated. For simple decompression in the setting of presumed distal obstruction, preoperative ultrasonography may suffice. **For percutaneous nephrolithotomy, the AUA guidelines on the surgical management of kidney stones recommends preoperative noncontrast CT for access and treatment planning** (Assimos et al., 2016). In cases in which ipsilateral renal function is uncertain, obtain a nuclear medicine renal scan.

Patient Positioning

There are a variety of positions in which patients can be placed for percutaneous access to the kidney. For practical purposes, the most common positions are prone, supine, and modifications of these positions. What follows is a description of the described positions for percutaneous renal access and a general comparison of the advantages and disadvantages of each. Comparisons particular to percutaneous nephrolithotomy are described in Chapter 94.

Prone Position

The prone position for percutaneous renal access, first described by Goodwin and colleagues in 1955, is the most commonly used position (Valdivia et al., 2011). In general, patients are positioned with the chest supported by either a single horizontal chest roll across the nipple line or two vertical rolls positioned along the mid-clavicular line. It is important to elevate the legs to prevent pressure injury of the lower extremities. Typically, the ipsilateral arm relative to the side of the procedure is positioned toward the head in a modified swimmers position, and the contralateral arm is tucked at the side. Meticulous padding of all pressure points is vital to prevent injury.

The prone position affords direct access into the favorably located posterior renal calyces. Any polar location can also be accessed (upper, mid, or lower). In particular, the upper pole calyx is anatomically closest to the skin in the prone position and offers ready access to the proximal ureter and in some cases, the entire collecting system (Ray et al., 2009). Prone positioning allows bilateral percutaneous procedures without any repositioning (Desai et al., 2007). Finally, if the chest is padded in such a way to allow free abdominal excursion (Fig. 12.8), prone positioning is associated with increased pulmonary capacity and no difference in peak inspiratory pressures relative to supine positioning (Edgcombe et al., 2008; Siev et al., 2015). Despite these benefits, there are several disadvantages to the prone position. From an anesthesia perspective, access to the airway is more challenging in the prone position. It is also associated with a decrease in cardiac index (Hatada et al., 1991). Although uncommon, there are extreme circumstances in which patients with spinal deformity or super morbid obesity cannot be safely positioned prone. Care must be taken when the patient is positioned prone to avoid pressure injuries, which in extreme situations can lead to rhabdomyolysis or neuraxial injury. In particular, ocular injuries resulting from insufficient padding are unique to the prone position (Ghani et al., 2016). Finally, prone positioning requires the surgeon to stand and work with outstretched arms, which can contribute to surgeon fatigue.

Supine Position

First described by Valdivia Uria and colleagues in 1987, the supine position is an alternative to traditional prone positioning (Valdivia Uria et al., 1987). As originally described, the patient is positioned with the ipsilateral side toward the most lateral aspect of the table and the flank elevated with a bolster or 3-liter bag of saline underneath the lumbar fossa. The ipsilateral arm is positioned across the chest, and padding is applied to limit pressure to the elbow and wrist. There have been several modifications to the prone position including the Galdakao-modified supine position (Scoffone et al., 2008) and the complete supine position (Falahatkar et al., 2011), among others.

Benefits of the supine position include easy access to the airway and optimization of cardiopulmonary function in patients. Because patients do not need to be repositioned after induction of anesthesia, randomized controlled trials indicate that supine positioning is associated with faster operative times (Al-Dessoukey et al., 2014), at least in the setting of percutaneous nephrolithotomy. Finally, radiation exposure to the physician's hands is minimized, and the surgeon can perform the procedure in the seated position, limiting fatigue. Drawbacks to the supine approach include limited surface area for renal puncture, difficulty accessing the upper pole, and lower intrarenal pressures caused by the downward orientation of the access sheath, which may impair visualization.

Modifications to Prone or Supine Positioning

From either position, better access to the urethra can be facilitated by positioning the patient with the legs spread in the prone split leg position (Grasso et al., 1993) or in a modified lithotomy position while in supine position. These modifications allow for a combined antegrade and retrograde approach at the time of percutaneous renal surgery. The clinical benefits of these modifications are unclear.

Anesthetic Considerations

Choice of anesthetic is typically left to the anesthesiology team and should be dictated by patient characteristics such as cardiopulmonary comorbidity and body mass index. In general, general endotracheal anesthesia is required to maintain a secure airway in the prone position, whereas laryngeal mask airway can be considered when the patient is positioned supine. Regardless of what primary anesthesia is used for percutaneous renal surgery, the addition of local and regional anesthesia may be beneficial. A meta-analysis of six randomized trials revealed reduced analgesia requirement and 24-hour pain scores in the patients receiving tract infiltration with local anesthetic (vs. placebo) (Wang et al., 2016). Additionally, intercostal nerve blocks and thoracic paravertebral block with long-acting local anesthetics have provided similar benefit in randomized controlled trials (Ak et al., 2013; Honey et al., 2013; Ozkan et al., 2013).

Choice of Calyx for Access

Choice of calyx for access is dictated by patient positioning; If the patient is prone, then the posterior calyces are most accessible, whereas if the patient is supine, then the anterior ones are preferred. In special circumstances (i.e., calyceal diverticulum), anterior or posterior calyces can be approached from any position. Access should never be directly through the renal pelvis, and caution should be exercised when puncturing in a location with atrophic renal parenchyma as sealing of the tract can be compromised.

Upper Pole Calyx

Puncture into the upper pole calyx provides the most versatile access. The renal pelvis, proximal ureter, lower pole, and in some cases, interpolar calyces can be accessed with a combination of rigid and flexible instruments with a well-placed upper-pole puncture. This site often requires supracostal (above the 12th rib) access leading to an increased risk for pleural morbidity. **Nonetheless, if entry directly above the 12th rib (11th intercostal space) provides the best access to the optimal calyx, then the benefit generally exceeds the risk** (Fig. 12.9). Entry above the 11th rib, however, has a greater potential for pleural and even lung injury, so when the best access calls for a direct puncture above the 11th rib, additional maneuvers should be considered to displace the kidney inferiorly. These include cephalad tilt of a subcostal access sheath or access needle placed into a lower calyx (Karlin and Smith, 1989; Lezrek et al., 2011); gentle traction on a through-and-through guidewire placed through a lower-pole access (Goyal et al., 2012); and attaining access during full inspiration (Falahatkar et al., 2010). Another alternative is to angle the access tract cephalad from a subcostal entry site (Liatsikos et al., 2005; Rehman et al., 2008). This approach provides limited access to the rest of the kidney. All of these alternatives can damage the kidney if excessive force is applied. Access above the 10th rib is associated with a high incidence of pleural violation and lung injury and should be avoided unless absolutely necessary. Thorascopically guided access superior to the 10th rib can be performed to reduce the risk for lung injury (Finelli and Honey, 2001).

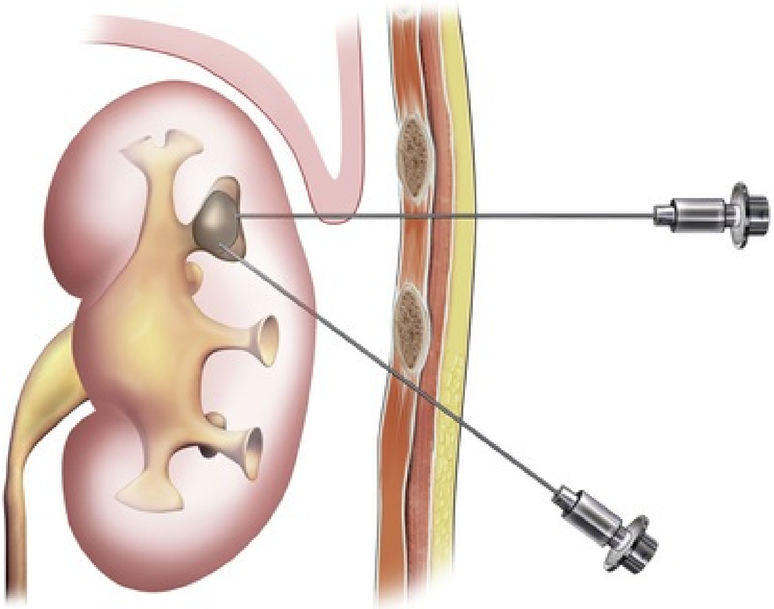

FIG. 12.9 Subcostal and supracostal percutaneous access to an upper pole calyx. The supracostal approach provides more direct access and provides a better angle for endoscopy of the rest of the kidney.

Interpolar Calyx

Interpolar calyceal access likely is the least versatile. Although it does afford ready access for procedures in the renal pelvis or upper ureter, it is nearly impossible to navigate a rigid instrument into the upper or lower pole calyces, so it otherwise should be reserved only for procedures limited to the interpolar region.

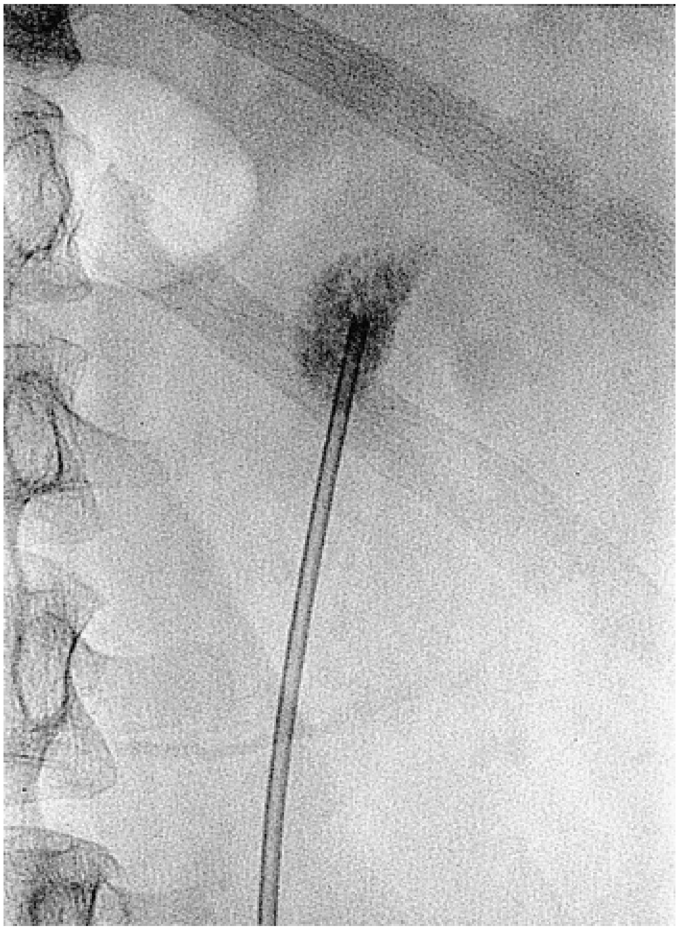
Lower Pole Calyx

Though not as versatile as the upper pole access, puncture into the lower pole calyx affords the surgeon ready access to the majority of the kidney while essentially eliminating the possibility of pulmonary morbidity with upper-pole access. A rigid instrument can often be navigated to the renal pelvis without much difficulty, though other bodily landmarks such as the iliac crest may limit upward deflection of the scope. With the use of a flexible scope, access to most calyces can be achieved.

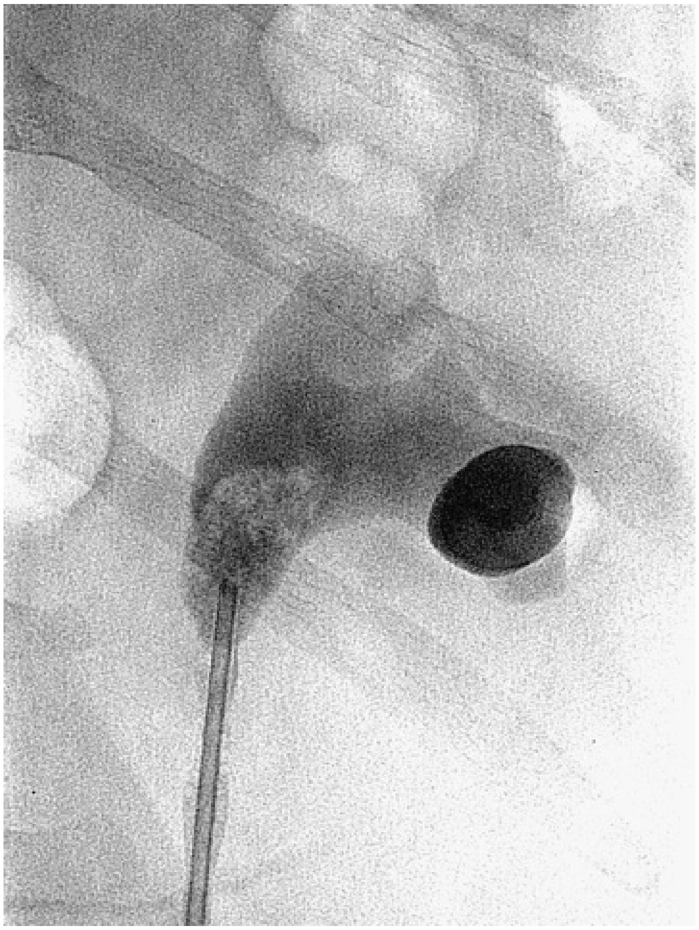
Image Guidance for Puncture

Fluoroscopic-Guided Access.

Fluoroscopic guidance is one of the most commonly employed techniques for antegrade access into the renal collecting system. **Fluoroscopy provides excellent delineation of the intrarenal collecting system anatomy and pathology (when contrast-enhanced), a wide field of view (that can be collimated down to reduce radiation exposure), and the ability to monitor all steps of the procedure. Although retrograde instillation of air and/or contrast material is not absolutely essential** (Tabibi et al., 2007), **most urologists find that it enhances fluoroscopically guided percutaneous access** (eFigs. 12.10 and 12.11).



EFIG. 12.10 Straight ureteral catheter has been passed up into stone-containing renal pelvis.



EFIG. 12.11 Retrograde pyelogram with air and contrast shows air in upper pole compound calyx and posterior lower pole calyx.

There are two well-described methods of fluoroscopic guidance for antegrade percutaneous access into the upper urinary tract collecting system: the "eye-of-the-needle" technique (Video 12.1▶) **and the "triangulation" technique** (Miller et al., 2007). Both have their proponents, and there is no clear advantage of one over the other, as confirmed by one randomized controlled trial (Tepeler et al., 2012).

In the remainder of this section, the descriptions are for percutaneous access in the prone position. Slight modifications are made for the supine position. First, place a retrograde ureteral catheter through which contrast material is instilled after obtaining an initial radiograph to delineate any pathology that may become obscured with contrast material. Combining the original noncontrasted images with the postinjection images is usually sufficient to identify an appropriate calyx for puncture. In some cases, it may be useful to perform an "air pyelogram" as an adjunct to retrograde pyelography by injecting a bolus of air to delineate the posterior calyces (in the prone position) (Fig. 12.12).

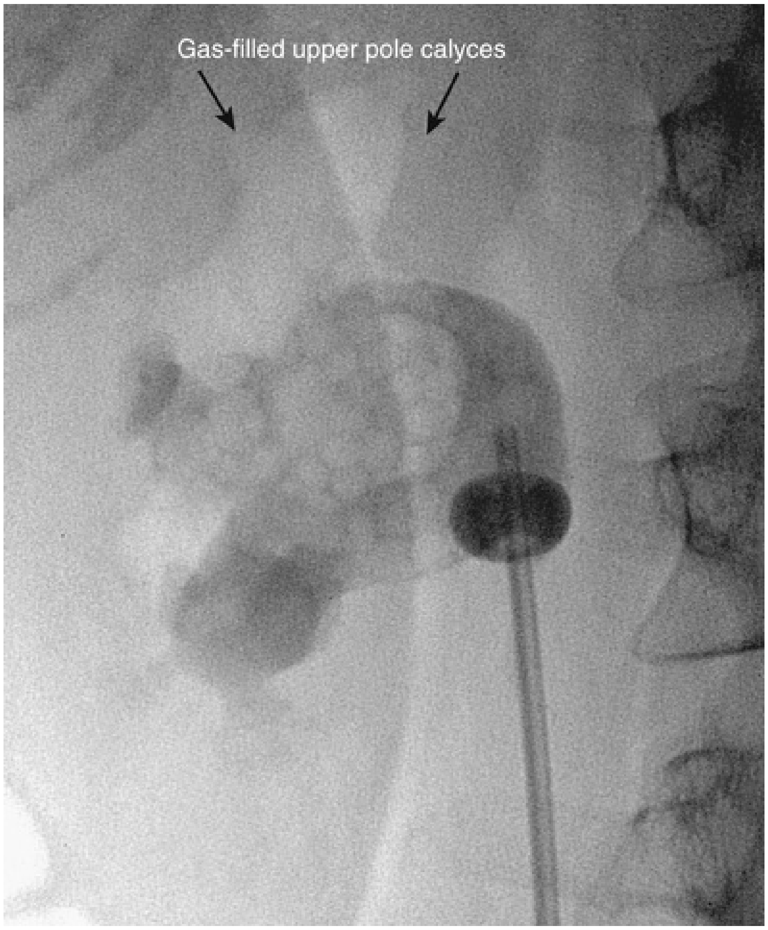


FIG. 12.12 Injection of air into contrast-filled upper tract collecting system shows posterior calyces, in this case most clearly the upper pole calyces.

To perform the “eye-of-the-needle” technique, first inspect the kidney with the fluoroscopy unit directly above the patient (directed vertically) and select the desired calyx. Next, rotate the top of the fluoroscopic unit 30 degrees toward the operator, which brings the fluoroscopic view approximately in line with the posterior calyces. The unit can be additionally rotated slightly cephalad or caudad to correspond more exactly with the calyx. Place the tip of a hemostat on the skin, and move it until it is directly over the desired calyx. Mark this site, and make an incision large enough to accept the needle and initial dilators. Place the tip of the access needle into this incision, and then move the shaft of the needle while keeping the tip in place until the needle is directly in line with the axis of the fluoroscopy unit; doing so gives the appearance of a “bull's eye” with the hub of the needle (which appears as a circle) around the shaft (which appears as a dot). The fluoroscopic view is as if the operator is looking down the shaft of the needle at the targeted calyx—thus the term *eye of the needle* (Fig. 12.13A). Advance the needle straight in while checking with fluoroscopy and adjusting the angle of the needle as needed to maintain the “bull's-eye” appearance. If the needle is more than a few centimeters deep and readjustment is necessary, the needle may have to be withdrawn before a new trajectory can be followed. The 21-gauge needle can be difficult to control during this step. If this occurs, substitute the more easily passed 18-gauge needle. Once the needle's axis is fixed and it is thought that the needle is approaching or is in the kidney (typically a “pop” can be felt when the renal capsule is punctured), then rotate the fluoroscopy unit away from the operator, back to vertical or even 10 to 15 degrees beyond vertical. Now the needle appears “in profile” as a straight line. With the cephalo-caudad and medial-lateral axes of the needle now fixed, advance or withdraw the needle to change its anterior-posterior position (depth) to get the tip of the needle into the desired calyx (see Fig. 12.13B). Aspiration of urine or air after removing the obturator confirms entry. Instillation of contrast material can be used to confirm entry as well, but if the needle is misplaced, the extravasated contrast material can obscure subsequent fluoroscopic visualization. If a gently passed guidewire stays within the contours of the collecting system, then this confirms proper entry without risking the troublesome extravasation of contrast material.

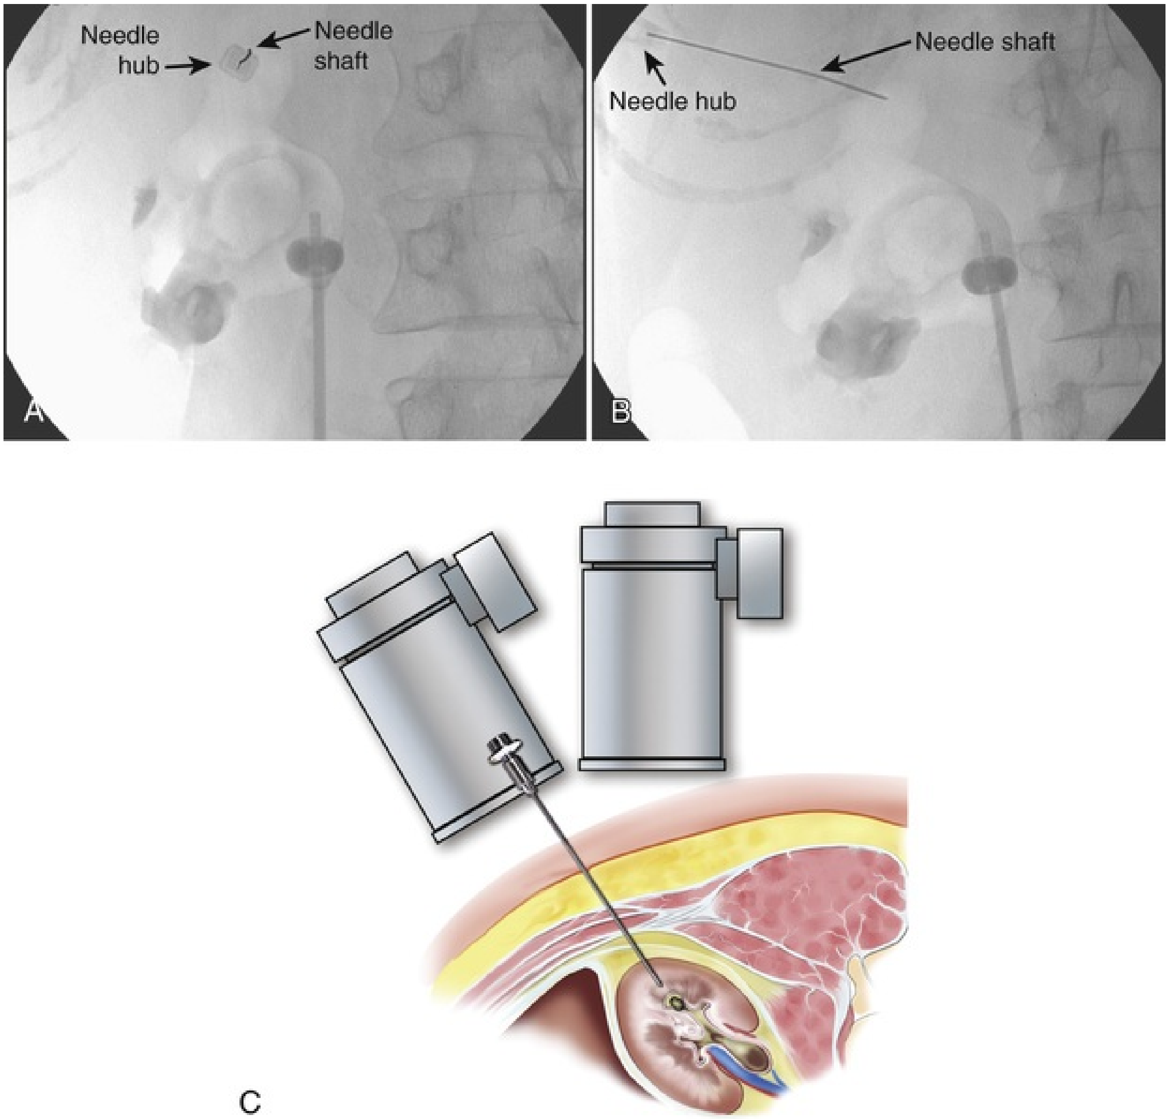

FIG. 12.13 “Eye-of-the-needle” fluoroscopic guidance. (A) With the top of the fluoroscopic unit rotated 30 degrees toward the operator, the needle is lined up directly over the intended calyx of entry. (B) With the fluoroscopy unit rotated away from the operator, the needle is now seen in profile and in (C) has already been advanced under fluoroscopic control to achieve collecting system entry.

To use the triangulation technique, inspect the kidney with the fluoroscopy unit directly above the patient to select the desired calyx, and hold the needle in the approximate position of the desired angle of entry. For puncture into a lower pole calyx, angle the fluoroscopy unit caudally to get the operator's hands outside of the radiation field. Triangulation relies on two distinct fluoroscopy unit positions to address both medial-lateral orientation of the needle and depth. First, with the unit rotated 20 to 30 degrees toward the operator, adjust the needle in the medial-lateral plane relative to the patient until the desired calyx is targeted (Fig. 12.14A). Once this orientation is satisfactory, rotate the unit away from the operator 20 to 30 degrees (toward a true anterior-posterior orientation). In this plane, adjust the needle in the cephalo-caudal plane relative to the patient until the desired calyx is targeted (see Fig. 12.14B). Move the needle only in the medial-lateral or cephalo-caudal plane in each projection, otherwise targeting will be compromised. Resting the forearm on the patient's back helps stabilize the needle in one plane while moving in the other. Once targeting is complete, advance the needle with the fluoroscopy in the anterior-posterior orientation to allow monitoring of needle depth. Assess the medial-lateral orientation of the needle with the fluoroscopy unit tilted toward the surgeon 20 to 30 degrees when the needle tip depth has reached the renal capsule to ensure that targeting is still appropriate. Confirm final entry into the collecting system in the anterior-posterior orientation.

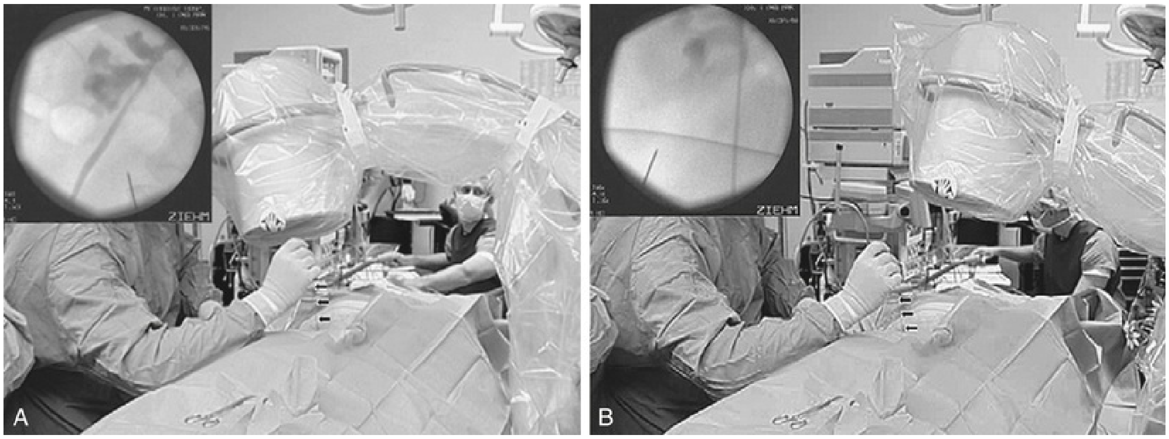

FIG. 12.14 Triangulation fluoroscopic guidance. (A) With the top of the fluoroscopy unit rotated laterally and cephalad, adjust the access needle *(arrows)* to a mediolateral orientation of the needle. (B) After rotating the top of the fluoroscopy unit medially, and while keeping mediolateral orientation of the needle constant, move the needle in the cephalo-caudad plane until the needle is again aimed toward the desired calyx. (From Miller NL, Matlaga BR, Lingeman JE: Techniques for fluoroscopic percutaneous renal access. *J Urol* 178:15–23, 2007.)

With the “eye-of-the-needle” technique, the proper cephalo-caudad and medial-lateral axes of the needle are verified and maintained on a single fluoroscopic view, and the confirmatory view is necessary only to confirm the depth of the needle tip. For the triangulation technique, one fluoroscopic view is used to assess the medial-lateral axis and another is used to assess the cephalo-caudal axis, with the depth of the needle tip being assessed on both views (Miller et al., 2007). The advantages of the triangulation technique over the eye-of-the-needle technique is that the needle cannot be passed too deeply because the depth of advancement is monitored continuously, and the tract is often oriented favorably in relation to the calyx of the puncture, avoiding excess torque on the kidney when working with rigid instruments. The disadvantage of the triangulation technique is that maintaining both the medial-lateral and cephalo-caudad planes is difficult because neither are monitored at the same time as in the eye-of-the-needle technique. Use of the 18-gauge rather than a 21-gauge needle is recommended with the triangulation technique to help maintain the angle of entry. Mechanical devices that stabilize the needle during insertion might be helpful as well (Lazarus and Williams, 2011).

Ionizing radiation presents a small but real risk. When the operator must grasp the access needle within the fluoroscopy field, it is best to hold the needle with a hemostat, sponge forceps, or purpose-built needle holder to reduce radiation exposure to the operator's hand. Collimating the field down as much as possible while still maintaining an adequate field of view reduces radiation exposure to the patient and all personnel in the room. Moving a collimated field around to maintain the object of interest in the field is preferable to maintaining a wide field that includes the operator's hands and unnecessary body parts of the patient. Increased body mass index, greater stone burden, nonbranched stones, greater number of access sites, and use of air rather than contrast during initial retrograde pyelography are associated with an increased radiation dose (Lipkin et al., 2011; Mancini et al., 2010). For additional information about radiation safety, see Chapter 157.

Ureteroscopic-Assisted Fluoroscopic Access.

As detailed earlier, placement of a ureteral catheter facilitates antegrade fluoroscopic access by allowing the surgeon to instill contrast material or air into the collecting system to choose a suitable target. Adaptations to this approach include placement of a ureteral access sheath through which a ureteroscope is introduced directly into the collecting system. This serves two purposes. First, the improved drainage afforded by the ureteral access sheath allows any stone fragments that may be generated during lithotripsy to flush down the ureter and out of the body (Landman et al., 2003). Second, a ureteroscope passed retrograde can greatly facilitate percutaneous entry into the intrarenal collecting system (Grasso et al., 1995; Kidd and Conlin, 2003; Patel et al., 2008) by allowing the surgeon to observe and correct the percutaneous placement of a needle into the desired calyx. A basket can then be passed through the ureteroscope to grasp the end of the percutaneous guidewire; pulling this out, the urethra provides through-and-through access (Fig. 12.15). Furthermore, tract dilation can be observed in real time, ensuring accurate working sheath placement. Moreover, the ureteroscope may have better access to some sites in the kidney than the nephroscope and can be used to assist in the procedure (e.g., fragment or relocate stones, fulgurate small tumors). Retrospective nonrandomized comparisons of ureteroscopic assistance versus solely fluoroscopic guidance for access during percutaneous nephrolithotomy suggest that the former may be associated with a lower transfusion rate (Sountoulides et al., 2009) and a decreased need for fluoroscopy time, multiple accesses, and early termination of the procedure resulting from hemorrhage (Isac et al., 2013).

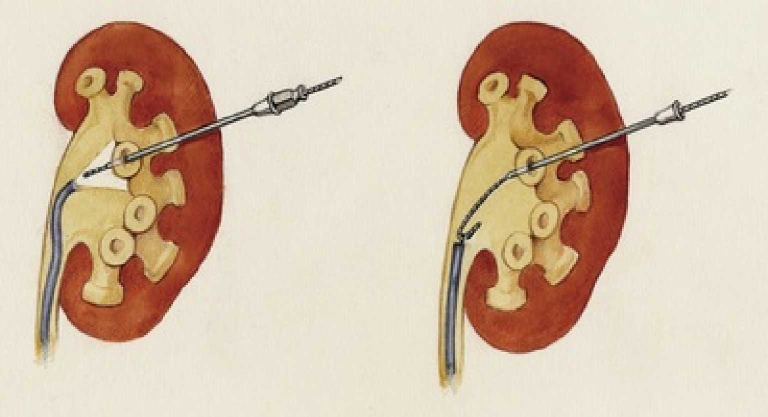

FIG. 12.15 Ureteroscope retrograde assistance. The needle can be directly visualized entering the calyx, and a wire can be grasped and pulled down the ureter and out the urethra.

More recently, use of the holmium laser to provide retrograde-assisted percutaneous renal access has been described. In a small study, investigators positioned a ureteroscope into the most posterior upper-pole calyx (confirmed by air bubble location) and used a 365-micron holmium laser fiber with settings of 1 Joule and 10 Hertz to bore directly through the desired calyx until the laser fiber was seen exiting the flank. At this time, a skin incision was made and an 18-gauge needle was advanced coaxially over the laser fiber until it was seen under direct vision to be entering the calyx. The laser fiber was then withdrawn and a guidewire was advanced antegrade, grasped with the ureteroscope, and withdrawn to secure through-and-through access (Kaler et al., 2018).

Ultrasound-Guided Access.

Although not as commonly performed as fluoroscopic guidance in the United States, ultrasound-guided renal access is widely practiced among the international urologic community. **Benefits of the ultrasound-guided approach include decreased ionizing radiation exposure, potential for decreased costs** (Hudnall et al., 2017), **ability to identify and potentially avoid adjacent viscera, and clear delineation of anterior versus posterior renal calyces.** It has been successfully performed in a variety of clinical situations including the pediatric population, those with obesity, and those with renal anatomic abnormalities (Penbegul et al., 2013; Usawachintachit et al., 2016; Xiao et al., 2016). Unlike fluoroscopically guided renal access, which is dependent on placement of a retrograde ureteral catheter for instillation of contrast, ultrasound-guided access can be performed in nearly any clinical situation. It is particularly useful in the setting of prior urinary reconstruction like ileal conduit or orthotopic urinary diversion, where access to the ureter may be impossible. A curved array ultrasound transducer, typically 3.5 MHz, is often utilized (Fig. 12.16). It is important to use an etched needle, which is more visible sonographically, to allow continuous visualization of the needle tip. The procedure begins with careful sonography of the kidney to determine appropriate access location. In a nondilated system, placement of a ureteral catheter allows for saline injection to distend the collecting system and facilitate accurate entry. Several techniques for ultrasound-guided access have been described, but in general, can be broken down simply into whether the ultrasound probe is oriented in a transverse or longitudinal orientation to the kidney. In the transverse orientation, orient the probe perpendicular to the paraspinous muscle. After selecting a target calyx, insert the needle orthogonally to the probe and track the needle continuously by sweeping the probe along the axis of the kidney. For the longitudinal approach, orient the probe cephalocaudally approximately parallel to the paraspinous muscle along the axis of the kidney. Insert the needle above or below the probe, and again track the needle until entry into the target calyx (Chu et al., 2016). Once entry into the collecting system is confirmed, fluoroscopy can be used for safety wire placement and tract dilation. A “fluoroscopy-free” approach wherein safety wire placement and tract dilation are conducted exclusively with ultrasonography has been described (Sharifiaghdas et al., 2015).

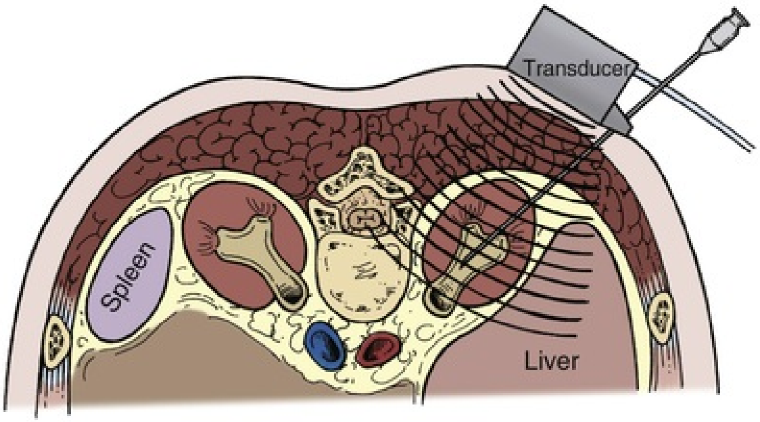

FIG. 12.16 Ultrasonographic guidance of puncture needle.

Advanced Guidance Techniques

In some complex cases, percutaneous access into the kidney guided by CT or MRI might be considered. The initial access is obtained into the desired calyx with the patient on the CT or MRI table, like the techniques used for needle biopsy (Barbaric et al., 1997; Hagspiel et al., 1998; Thanos et al., 2006). Bowel and other viscera can be imaged to protect against their injury, and this approach is especially useful in cases of anatomic abnormalities (LeMaitre et al., 2000; Matlaga et al., 2003; Srivastava et al., 2010).

“Blind” Access.

The upper urinary tract collecting system can also be accessed “blindly,” without any imaging guidance (Chien and Bellman, 2002). The only situation in which this should be considered is if sonography is not available and there is complete ureteral obstruction (precluding retrograde instillation of contrast material or opacification of the collecting system with intravenous contrast). The lumbar notch, also known as the *superior lumbar triangle* or *Grynfeltt lumbar triangle,* has been reported to be a reliable landmark for blind percutaneous renal access (Fig. 12.17). The lumbar notch is an area of muscular insufficiency through which hernias can occur. It is located posteriorly below the 12th rib. The superior border is the 12th rib and latissimus dorsi muscle, the lateral border is the transversus abdominis and external oblique muscles, the medial border is the quadratus lumborum and sacrospinalis muscles, and the inferior border is the internal oblique muscle. Insert a needle 3 to 4 cm deep into the notch at a 30-degree cephalad angle to enter the collecting system. Another blind approach to the collecting system is to insert a needle directly perpendicular to the body surface 1 to 1.5 cm lateral to the L1 vertebral body, which will lead directly to the renal pelvis if anatomy is normal. If fluoroscopy is available, then air and contrast material can be injected through a blindly placed needle to fluoroscopically assess its position and guide another needle if needed. In the only randomized clinical trial comparing “blind” access to image-guided access, entry into the collecting system was successful in 50% and 90% of cases, respectively (Basiri et al., 2007). Use of the technique is not recommended in most settings.

FIG. 12.17 The lumbar notch is a useful anatomic landmark for blind percutaneous access to the renal collecting system. It is bounded superiorly by the latissimus dorsi muscle and the 12th rib, medially by the sacrospinalis and quadratus lumborum muscles, laterally by the transversus abdominis and external oblique muscles, and inferiorly by the internal oblique muscle.

Key Points: Obtaining Percutaneous Renal Access

- Whether the interventional radiologist or urologist obtains percutaneous renal access, it is imperative that the urologist is present to clearly define the best location for puncture.
- Fluoroscopy and ultrasonography are well-described techniques to guide percutaneous renal access. In some cases, advanced techniques are required to safely obtain renal access.
- Upper-pole access is often the most versatile location for percutaneous renal surgery as all calyceal groups are typically able to be reached. Upper-pole access must be balanced with the risk for pleural morbidity.

Access Needles.

The general scheme of antegrade access is to place a needle through the skin into the upper urinary tract collecting system. A guidewire is placed through the needle, and then catheters and other devices are placed over the guidewire, eventually enlarging the tract until the desired lumen is obtained. This is the Seldinger technique, described (for vascular access) by Sven-Ivar Seldinger (Seldinger, 1953). The standard choices for the needle are a 21-gauge needle through which is passed a 0.018-inch guidewire or an 18-gauge needle through which is passed a standard 0.035-inch guidewire. Both needles have a blunt sheath and a sharp obturator (Fig. 12.18). The 21-gauge needle has the advantage of causing relatively minor injury as it is passed through tissue. Multiple passes can generally be made with little risk for hemorrhage from the needle itself. The 18-gauge needle is more traumatic, and multiple passes should be avoided. The advantage of the 18-gauge needle is that it is stiffer. In many circumstances, the 21-gauge needle does not adequately maintain trajectory (e.g., scarred kidney, obese patient), and the 18-gauge needle is more effective. In addition, the 0.018-inch guidewire that passes through the 21-gauge needle must be exchanged for a standard 0.035-inch guidewire for subsequent tract dilation or catheter placement. This requires an extra step, which adds to the complexity of the procedure and increases the risk for access loss. Balancing the reduced efficacy of the 21-gauge needle and its increased potential for loss of access versus the increased risk for trauma with the 18-gauge needle, it is recommended that the 21-gauge needle be used when the operator is less experienced or if minimizing trauma is paramount. The 18-gauge needle should be used when an experienced operator is confident that the tip of the needle can be placed within the desired calyx with just a few attempts.

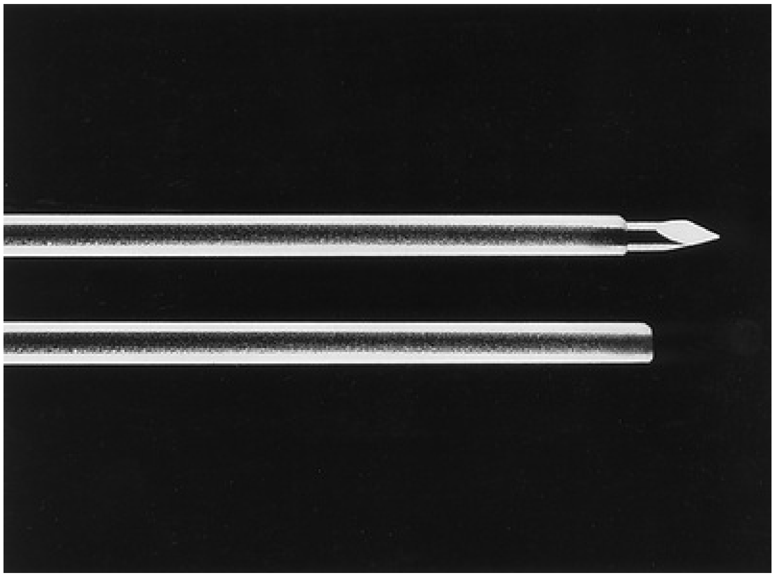

FIG. 12.18 Percutaneous access needle, with a blunt sheath and a sharp obturator.

Two methods can be used to exchange the 0.018-inch for a 0.035-inch guidewire. A coaxial introducer incorporates a small catheter within a slightly larger catheter. After inserting the 0.018-inch guidewire and removing the needle, advance the coaxial introducer over the guidewire until the end is within the renal collecting system. Remove the inner catheter and 0.018-inch guidewire, and then advance a 0.035-inch guidewire through the outer catheter into the collecting system. The second method is the use of a graduated introducer, which fits over the 0.018-inch guidewire at its tip but then enlarges to a lumen that will accept the 0.035-inch guidewire. A few centimeters back from the tip there is a hole through which the 0.035-inch guidewire can pass. After inserting the 0.018-inch guidewire and removing the needle, pass the graduated introducer over the guidewire until it is a few centimeters inside the kidney, such that the side hole is within the renal collecting system. Remove the 0.018-inch guidewire and then insert an angled or *J*-tipped 0.035-inch guidewire through the introducer until the end of the wire exits the catheter within the collecting system. With either the coaxial or graduated introducer, a stiffener can be used to assist in passing the device over the relatively insecure 0.018-inch guidewire.

Guidewires.

The safest initial 0.035-inch guidewire to use for upper urinary tract percutaneous access is a polytetrafluoroethylene (PTFE)-coated *J*-wire or *C*-wire. The curved tip makes the guidewire unlikely to perforate out of the collecting system. This guidewire will not easily pass down the ureter, however, which is more easily done with a floppy-tip PTFE-coated guidewire or a hydrophilic guidewire with a straight or angled tip. There are many options available to the surgeon to facilitate passage of the wire down the ureter and into the bladder. With an upper-pole calyceal puncture, the trajectory of access is often in line with the ureter, thus the wire may pass without assistance. In the case of a lower-pole calyx or when initial access to the ureter is not achieved, use of a torque-stabilized angled-tip catheter allows the surgeon to change the trajectory of the wire such that the ureter can be cannulated. Once a wire has been negotiated down the ureter, it is often exchanged for a stiffer wire (i.e., Amplatz super stiff wire) over which dilation is more readily achieved. In most situations, it is best to place a second safety wire down the ureter. This can be achieved by positioning either a dual-lumen catheter or larger coaxial catheter with an inner lumen sufficient to pass a second guidewire down the ureter. There are instances in which placement of a second guidewire is challenging such as complete staghorn calculi, calyceal diverticulae, and impacted infundibular stones. In these cases, working with just a single guidewire is appropriate, but attempts should be made to secure access down the ureter if ever feasible as the case progresses to avoid losing access.

Tract Dilation.

Once there is adequate wire access into the upper urinary tract collecting system, dilate the tract to allow insertion of working instruments. In most cases, the goal of dilation for percutaneous renal surgery is to place a 30-Fr inner-diameter/34-Fr outer-diameter plastic access sheath. In some cases, a smaller sheath with an inner diameter measuring 12 to 24 Fr is adequate. Renal access sheaths generally have a beveled tip, such that one side of the sheath extends farther than the other part. This bevel is used to maintain access into part of the collecting system on one side of the sheath while allowing extra mobility on the other side. Sheath repositioning is facilitated by the bevel. In cases of pathology at the edge of the collecting system, however, the bevel is a disadvantage because the entire tip of the sheath cannot be placed into the collecting system. Both opaque and clear sheaths are available; some prefer the clear sheaths because structures next to the sheath can be visualized.

In the early years of therapeutic percutaneous renal procedures, the tract was dilated gradually over the course of many days by placing sequentially larger tubes. Acute dilation of the tract was first reported by Castañeda-Zúñiga and associates in 1982 (Castañeda-Zúñiga et al., 1982). There are several dilator systems available. **Regardless of the method used, is it imperative that the dilator does not pass too far into the collecting system.** If this occurs, an infundibulum, the renal pelvis, or the ureteropelvic junction can be torn or perforated, either directly by the dilator or indirectly by a stone pushed aside by the dilator. Pass the dilator just into the calyx. It is better to dilate a bit “short” of the targeted calyx than to dilate too far and create trauma. If on initial nephoscopy the sheath is not deep enough, then simply replace the dilating device and redilate after advancing it. Dilators should not be used to dilate the skin; incise the skin to allow entry of the final sheath without pressure on skin edges.

Sequential rigid metal dilators, introduced by Alken (1985), are a series of progressively enlarging coaxial stainless steel rods that pass over an 8-Fr guide rod. The first step in tract dilation is to pass the 8-Fr guide rod over a 0.035-inch guidewire. The end of the guide rod has a ball that prevents advancement of the first dilating rod beyond the tip. The ball is positioned at the intended depth of the dilation (Fig. 12.19). After passing the first rod, each successive metal rod is passed sequentially over the former until the desired tract is achieved, up to a 30-Fr rod over which is passed a 30/34-Fr plastic sheath. **The advantages of the rigid metal dilator system are that it is the most effective dilator, that it is able to dilate even when there is dense perirenal scarring from prior procedures, and that it is inexpensive on a per-case basis because it is reusable. The disadvantage is that, for the same reason they are so effective, the rigid metal dilators can do considerable damage.** The depth of the dilation can be hard to maintain accurately, especially when pushing against tough scar tissue. One group has modified the rigid metal rods, tapering the ends and adding centimeter markings (Shen et al., 2007).

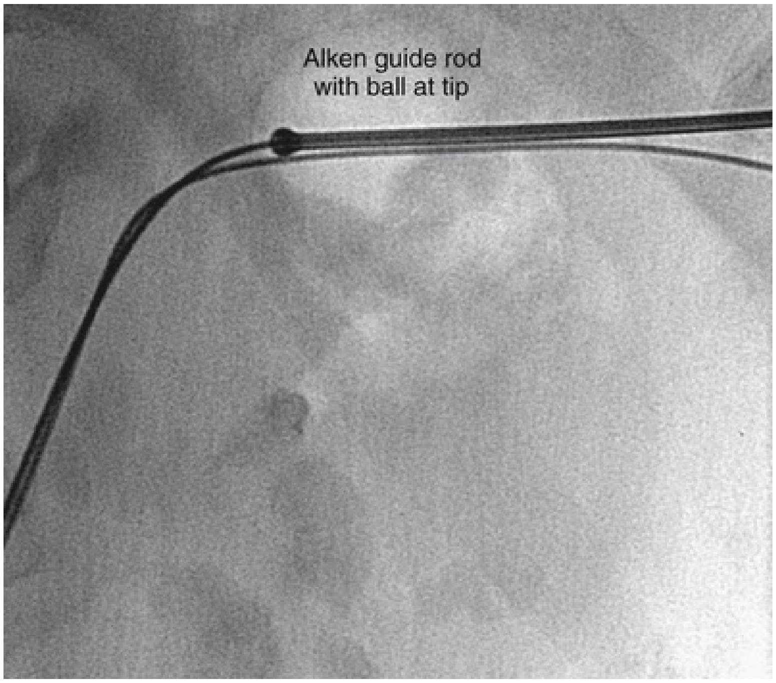

FIG. 12.19 Alken guide rod is positioned with the ball at the tip of the rod positioned at the intended depth of the dilation.

Progressive semirigid plastic dilation sets, often referred to as “Amplatz” dilators, after Kurt Amplatz, the senior author in the initial publication (Rusnak et al., 1982), consist of progressively larger firm polyurethane dilators that are passed over an 8-Fr PTFE guiding catheter that fits over a 0.035-inch guidewire (Fig. 12.20). The dilators are passed one after the other, not coaxially like the rigid metal dilators but progressively, advancing one dilator, removing it, advancing the next largest dilator, and so on until the final tract diameter is achieved. The working sheath is passed over the final dilator, and then the dilator and 8-Fr catheter are removed, leaving the working wire and sheath in place. The dilators are made in increments of 2 Fr, but if the tissue being dilated is soft, then not every dilator needs to be used. **The advantages of the semirigid plastic dilation system are that trauma to the collecting system is theoretically less likely than with the rigid metal dilators (although experienced urologists have found no difference between the two systems in terms of safety), but the disadvantage is that hemorrhage can occur each time a dilator is withdrawn.** Current semirigid plastic dilators are sold as disposable devices, so they are more expensive on a per-case basis than rigid metal dilators. One retrospective comparison of the two techniques found no other differences (Ozok et al., 2012).

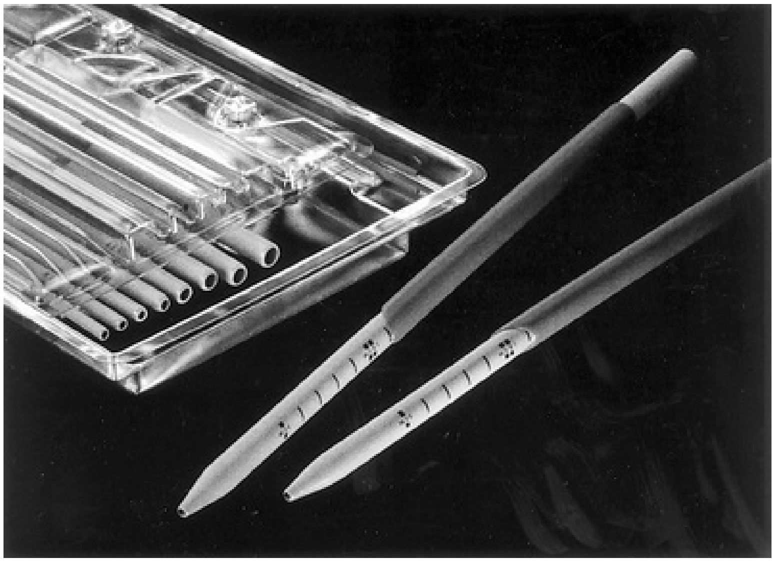

FIG. 12.20 Amplatz dilators with sheaths.

Balloon dilators (Fig. 12.21) do not require the repetitive passes of the rigid metal and semirigid plastic dilation systems. This is the most common dilation method for percutaneous renal surgery today (Benway and Nakada, 2008). The appropriate working sheath is backloaded onto the balloon dilation catheter, which is passed over the working wire until the radiopaque marker is at the intended depth of dilation (Fig. 12.22A). The dilating balloon is then inflated with a pressure syringe. A "waist" appears at the site(s) of greatest resistance, usually the abdominal wall fascia and the renal capsule (see Fig. 12.22B). Once the balloon is fully expanded (see Fig. 12.22C), the working sheath is advanced over the balloon (see Fig. 12.22D). The balloon catheter has a "shoulder," which is the portion between the end of the balloon and the point at which the maximal diameter is achieved. Passing the sheath beyond the maximal diameter of the balloon risks significant injury. **Balloon dilators, which are expensive one-time-use devices, are less effective than rigid metal and semirigid plastic dilation systems in densely scarred tissue but are more effective when the kidney is hypermobile** (Kumar and Keeley, 2008), though novel PTFE-reinforced balloons offering increased burst pressures may be useful in this setting. Most (Davidoff and Bellman, 1997; Heggagi et al., 1991; Kukreja et al., 2004; Safak et al., 2003) but not all (Gonen et al., 2008a; Wezel et al., 2009) single-series reports have suggested that hemorrhage and transfusion rates are less with the balloon dilators compared with rigid metal and semirigid plastic dilators. In a large multi-institutional study, however, balloon dilators were associated with longer operative time and greater bleeding and transfusion rates compared with rigid metal and semirigid plastic dilators (Lopes et al., 2011). Baseline differences between the groups, including more stones per kidney and more frequent treatment of staghorn calculi in the balloon dilation, may have been biased against balloon dilation.

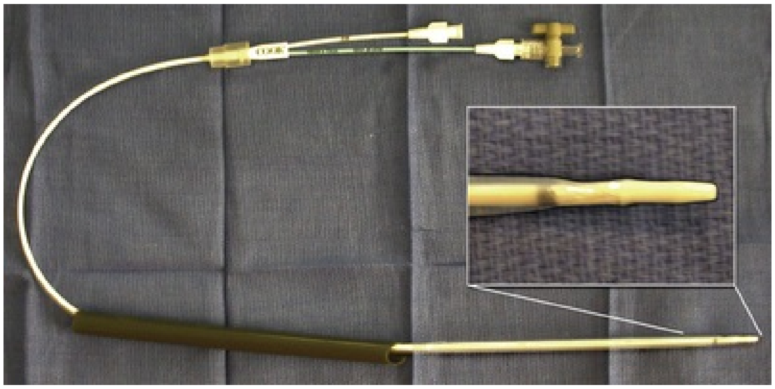

FIG. 12.21 Balloon dilation catheter with preloaded sheath.

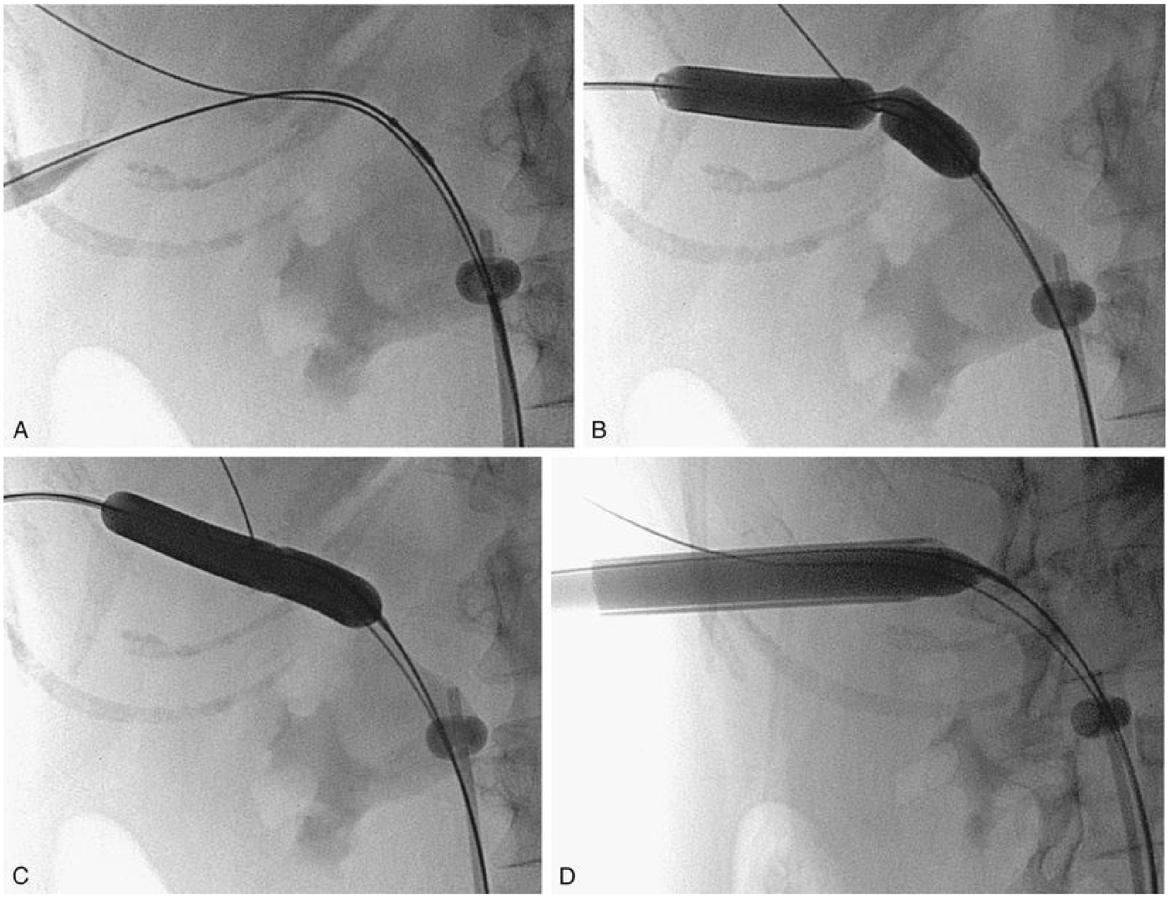

FIG. 12.22 Balloon dilation of tract and placement of working sheath. (A) Balloon catheter is inserted over wire, with distal radiopaque marker at the intended depth of dilation. (B) "Waist" appears as balloon is inflated. (C) Balloon is fully expanded. (D) Sheath is passed over balloon, taking care not to advance it beyond the point of maximal diameter of the balloon.

In an effort to further simplify dilation of the renal access tract, a number of single-step techniques have been described. The simplest is passage of the final semirigid plastic dilator without prior dilation by the smaller dilators (Frattini et al., 2001). A meta-analysis of four randomized controlled trials comparing single plastic dilators with sequential rigid metal dilators suggested that the former was associated with reduced access and fluoroscopy times without increased complications (Li et al., 2013c). Devices designed specifically for single-step dilation include a balloon dilator with an expandable sheath (Baldwin et al., 2006; Kalpee et al., 2012; Maynes et al., 2008; Pathak and Bellman, 2005) and a rigid dilator with an expandable sheath (Goharderakhshan et al., 2001). In the only randomized trial to compare all four dilation methods (balloon, rigid metal, semirigid plastic, and single-step), authors found no difference in access time, hemoglobin decrease, complication rates, or success, though fluoroscopy time was significantly decreased in the balloon-dilation and one-step-dilation groups (Srivastava et al., 2017).

The most common cause of difficult tract dilation is prior renal surgery (Joel et al., 2005). If even semirigid plastic or rigid metal dilators fail, novel uses of devices such as Collings knives, atherotomy cutting balloons, or fascial incising needles can be employed (Davis et al., 1991; Williams et al., 2008). One group has reported using a bipolar resectoscope with a plasma vaporization electrode to enlarge the percutaneous tract, and in their randomized controlled trial there were some advantages over balloon dilation (Chiang and Su, 2013). Though densely scarred kidneys such as those in the setting of repeat percutaneous renal surgery, present challenges, they are often not insurmountable, and surgery can be successfully performed in most cases (Borofsky et al., 2016).

Postprocedural Drainage

After percutaneous renal access and surgery, the surgeon must consider what, if any, means of drainage to employ.

Balloon Catheters.

The Foley and Council catheters used for transurethral drainage can be used as nephrostomy tubes as well (Fig. 12.23). These tubes come in a range of diameters; typically, 16- to 24-Fr catheters are used for postoperative nephrostomy drainage. **The 5-mL retention balloon might be too large for some collecting systems and does not need to be completely inflated.** The balloon can cause calyceal obstruction if it is pulled into an infundibulum. **Saline or water should be used to inflate the balloon because viscous contrast material might hinder emptying of the balloon when removal is attempted.** An advantage of the Council catheter is the ability to pass a small-caliber catheter through the end hole and down the ureter, providing more secure access to the upper urinary tract collecting system and maintaining ureteral patency. **All nephrostomy tubes, even ones with robust internal retention devices, should be fixed to the skin externally with a suture or other mechanism.** External fixation of a tube, however, does not necessarily prevent internal dislodgement of the tube. Especially in a large patient, the distance from the skin to the collecting system can change with patient movement, and the tube (fixed at the skin) can pull out of the kidney. **The potential for tube dislodgement is one of the best arguments in favor of nephrostomy tubes that have some extension down the ureter to maintain a conduit to the upper urinary tract collecting system even if the renal pelvic portion of the tube is pulled out of the kidney.**

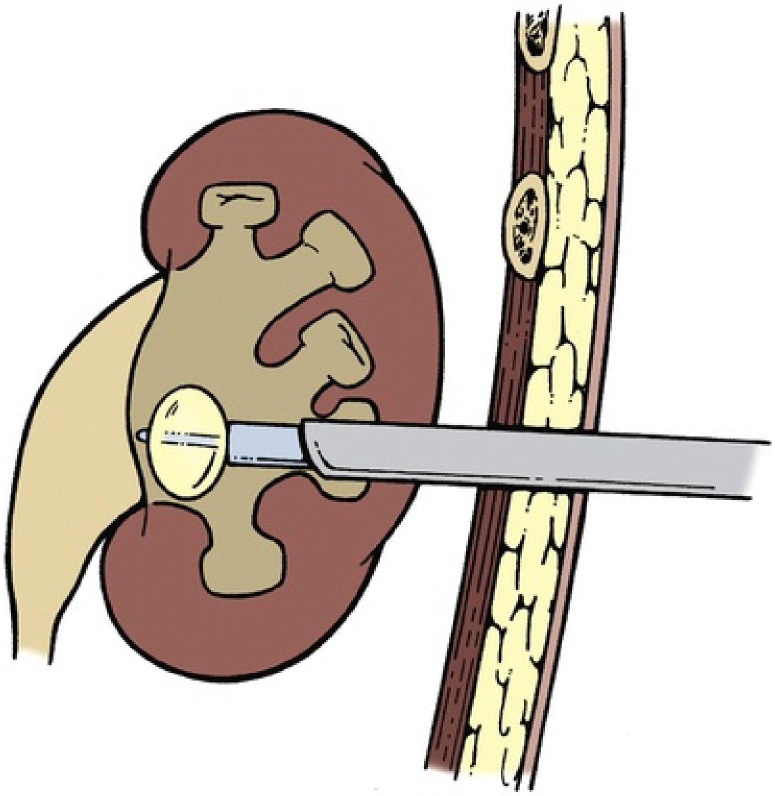

FIG. 12.23 Council catheter.

Cope Catheter.

A more secure retention mechanism is provided by Cope nephrostomy tubes. **A string exits the catheter a few centimeters from the distal tip and then re-enters the catheter near the tip** (Fig. 12.24). **Pulling on the string forms a secure coil that is not easily dislodged from the renal pelvis.** The string is fixed at the external end of the tube with a locking mechanism or by wrapping it around the tube and fixing it in place with a rubber cuff. Cope catheters employ the same coil shape used in pigtail ureteral stents. The active reinforcement of the coil strength by the string is thought to provide more secure retention than the passive coil of a pigtail, although one comparative study did not confirm this (Chuang et al., 2011). Cope nephrostomy tubes, ranging from 6 to 14 Fr in diameter, can be used for simple upper urinary tract drainage and instillation procedures and after percutaneous surgery. Care should be taken when placing a small-bore cope nephrostomy tube (8-10 Fr) after percutaneous renal surgery in which a large tract is dilated such as in percutaneous nephrolithotomy as the tube can become dislodged. The main risk factors for dislodgement is increased body mass index (Bayne et al., 2015). Risk for dislodgement can be reduced by placing the retention loop in a polar calyx rather than in the renal pelvis and by using a nephrostomy tube with extension down the ureter (see later).

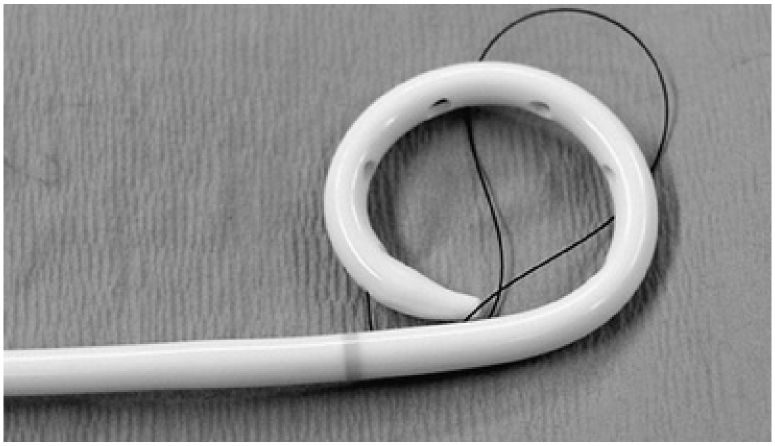

FIG. 12.24 Cope catheter with the retention string loosened for demonstration.

Malecot Catheter.

The wings of the Malecot catheter expand when the catheter is at rest, providing a modest but atraumatic and nonobstructive retention mechanism (Fig. 12.25A). When the catheter is being placed or removed, a stiffener is inserted through it to push on the distal end of the Malecot tip and straighten the wings. During removal, this stiffener can misalign with the Malecot tip if the tube is not straight; pulling the catheter back until the tube is straight helps the stiffener line up properly. **The Malecot catheter is also available with an extension that is directed down the ureter. This modification is called a "re-entry" catheter because it simplifies placing a guidewire through the Malecot catheter and down the ureter into the bladder** (see Fig. 12.25B). The extension is long enough (18 cm) so that in most patients the Malecot tube can be withdrawn until the wings are externalized and a guidewire can be placed into the ureter. Malecot catheters for renal use are large-bore catheters, ranging from 16 to 30 Fr, although Malecot catheters as small as 8 Fr are available.

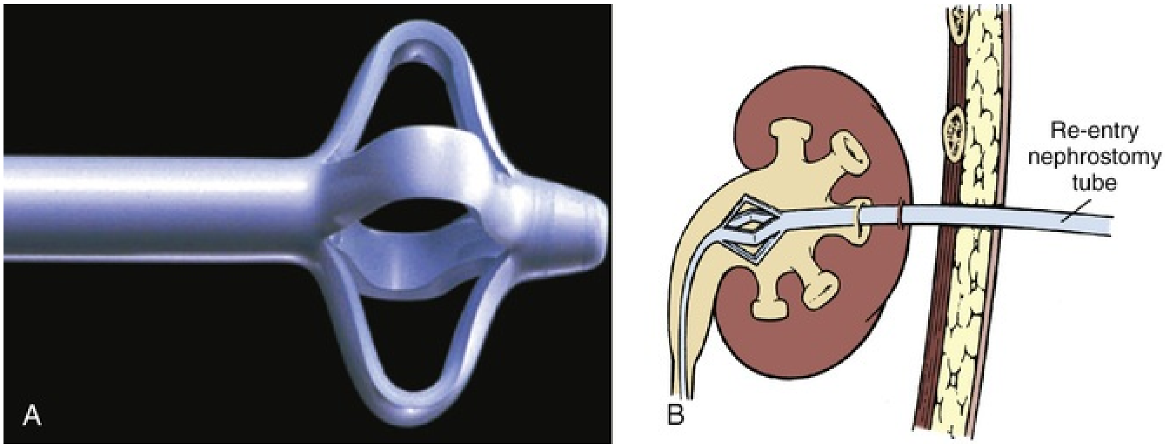

FIG. 12.25 (A) Malecot catheter. (B) Malecot catheter with ureteral extension (“re-entry” catheter).

Nephroureteral Stent.

The Cope retention mechanism is also used in nephroureteral stents. A nephroureteral stent has a renal coil like that of a Cope nephrostomy tube, but the tube continues to a ureteral extension that travels down the ureter to end in a passive pigtail that rests in the bladder (Figs. 12.26A, B). The ureteral portion can be the same diameter as the nephrostomy portion, or it can be narrower. A nephroureteral stent is passed percutaneously over a wire that ends in the bladder. Once the end is coiled generously in the bladder, careful inspection of the fluoroscopy image reveals the location of the side holes in the renal coil. By moving the catheter in and out while pulling on the string and rotating the external portion of the tube clockwise, the Cope retention coil is formed in the renal pelvis. **A nephroureteral stent offers excellent control of the entire upper urinary tract, from renal pelvis to bladder, and is unlikely to become dislodged.** Nephroureteral stents are available in diameters of 8 to12 Fr, and the standard lengths (from renal to bladder coil) are 20 to 28 cm.

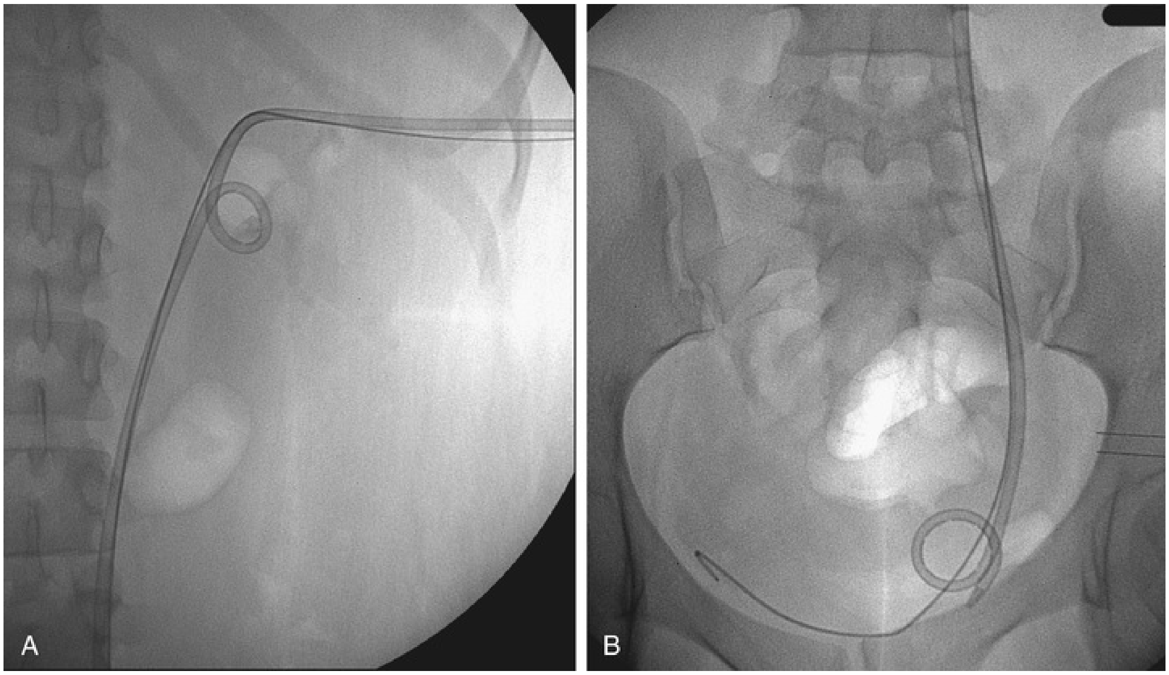

FIG. 12.26 Nephroureteral stent. (A) Renal coil. (B) Bladder coil.

Circle Catheter.

A final type of nephrostomy tube is the circle nephrostomy tube (Fig. 12.27), **which is secure, easily exchanged, causes little trauma, rarely occludes, and provides excellent drainage and an avenue for irrigation of the renal pelvis.** The circle nephrostomy tube requires two percutaneous access sites to the kidney, and this tube is most useful when maintenance of two tracts is desired, such as for irrigation of the renal pelvis or if more than one access is necessary for second-look nephroscopy (Kim et al., 2005). After obtaining access at two distant calyces, a flexible nephroscope or flexible ureteroscope passed over one wire is used to grasp the wire coming from the other site. When the endoscope is withdrawn, the wire is now in position to guide placement of the circle nephrostomy tube. Radiopaque markers on the tube delineate the location of the drainage holes, which should be maintained within the intrarenal collecting system. External drainage of the circle nephrostomy tube requires a Y-connector. Achieving repeat access into the kidney for second look nephroscopy is straightforward. A PTFE-coated wire is introduced into one end of the circle catheter until resistance is met or it exits through the other limb of the tube. If resistance is met, this is typically caused by the wire exiting through one of the side holes of the catheter. In this instance, the tube and wire are advanced together until the wire emanates from the other point of renal access (El Tayeb et al., 2017). Once through-and-through renal access is reestablished, tract dilation can be performed and second-look nephroscopy completed.

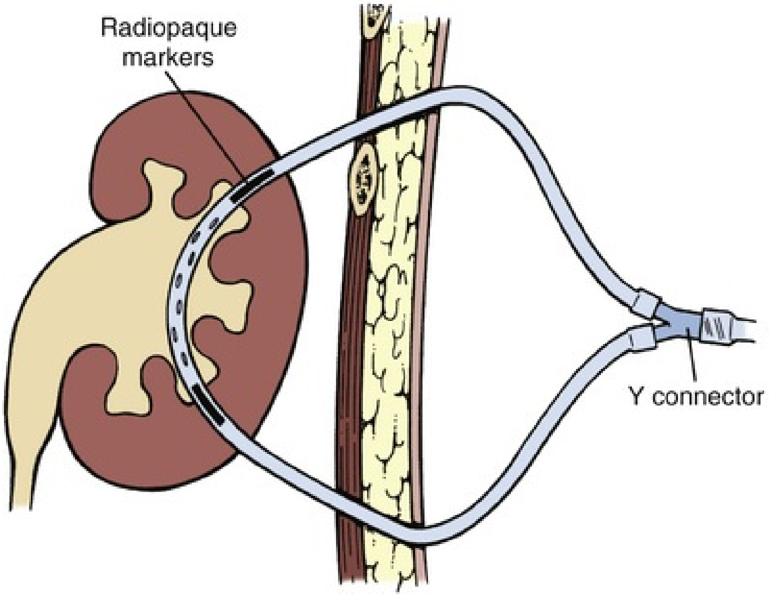

FIG. 12.27 Circle nephrostomy tube.

General Considerations.

The advantages of a postoperative nephrostomy tube include good drainage and control of the upper urinary tract and maintenance of percutaneous access for additional procedures. It was initially thought that a postoperative nephrostomy served to tamponade the nephrostomy tract and reduce hemorrhage, but subsequent studies have suggested this is not the case. When hemorrhage does occur, however, the larger caliber of a nephrostomy tube provides better drainage of the upper urinary tract collecting system than an internal ureteral stent. In addition, if a large perforation has occurred during the procedure, the additional diversion of urine away from the site might be advantageous. When a nephrostomy tube is left in place after percutaneous renal surgery, it is usually in the dilated access site. At least one group has attempted to reduce the discomfort associated with supracostal percutaneous renal surgery by placing a small-caliber postoperative nephrostomy tube in a new subcostal site and leaving the dilated supracostal access site without a nephrostomy tube (although there was no control cohort for comparison) (Kim et al., 2006).

Including, along with the nephrostomy, a tube that goes down the ureter provides the greatest control and assurance of drainage. Because entry of a tube into the bladder is associated with additional symptoms, such a tube should only be used when needed. Considerations include the size of the patient (which determines to a large extent the risk for tube dislodgement), the importance of maintaining drainage, and the desire for ureteral intubation (e.g., ureteral obstruction that might resolve if intubated, ureteral injury that should be bypassed). Aside from the choice of retention mechanism, the main remaining consideration is the diameter of the nephrostomy tube.

A number of studies have compared the impact of nephrostomy tube diameter after percutaneous renal surgery including two nonrandomized prospective trials (De Sio et al., 2011; Maheshwari et al., 2000) and four randomized controlled trials comparing large-caliber tubes (20 to 24 Fr) to small-caliber tubes (8 to 18 Fr) (Desai et al., 2004; Liatsikos et al., 2002; Marcovich et al., 2004; Pietrow et al., 2003). **Among the six studies comprising a total of 215 patients with nephrostomy tubes, five revealed less pain and two reported less urinary leakage in the patients with smaller tubes. Bleeding was not increased in the groups with smaller tubes in any of the studies.** Only one study found no benefit to the smaller tube (Marcovich et al., 2004). Although tube diameter is not related to bleeding overall, the removal of larger tubes occasionally can be followed by immediate hemorrhage; this is rare with smaller tubes. As such, large-caliber nephrostomy tubes should be removed in a radiology suite where there is the opportunity for immediate replacement of the tube. Small-caliber tubes can be removed safely at the bedside after a period of clamping to assess clinically for distal ureteral obstruction.

“Tubeless” With Ureteral Stent.

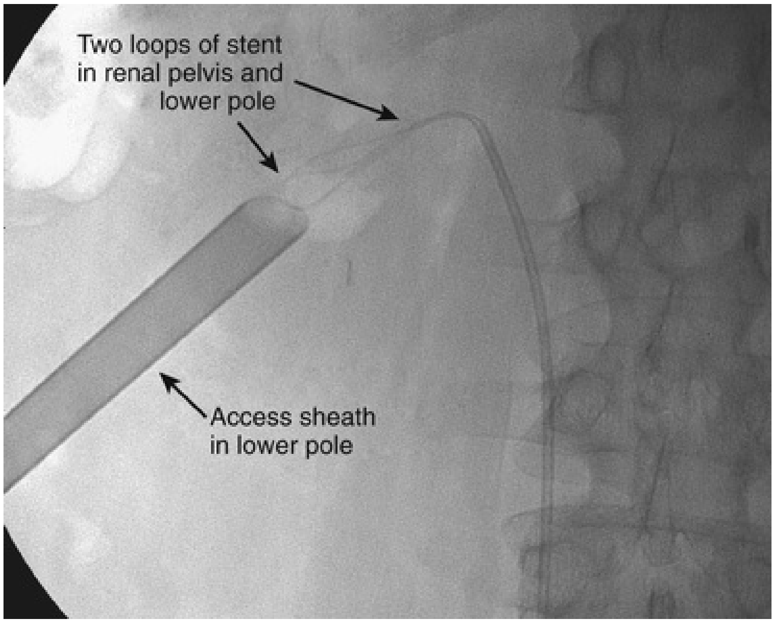
A “tubeless” percutaneous procedure—one that omits the postoperative nephrostomy tube—was initially proposed by Wickham and colleagues (1984). This practice never met with widespread acceptance, especially after Winfield and colleagues (1986) reported disastrous outcomes with this technique. The concept was revived in 1997 by Bellman and colleagues (1997) with the addition of an internal ureteral stent left in place for 1 or 2 weeks. Since then, many studies have evaluated the practice of omitting the nephrostomy tube after percutaneous renal surgery. Although this technique is called “tubeless,” most series employ a ureteral stent for a short period postoperatively.

Options for ureteral stenting without a nephrostomy tube after percutaneous renal surgery include an internal ureteral stent that is removed cystoscopically, an internal ureteral stent with an attached string that exits out the flank to allow removal of the ureteral stent without cystoscopy, and an externalized (out the urethra) ureteral stent that is removed along with the urethral catheter to which it is attached. The potential advantages of omitting the nephrostomy tube after percutaneous renal surgery include decreased pain and analgesic use, avoidance of an external drainage device, abbreviated hospital stay, and decreased health care costs (secondary to shortening the duration of hospitalization). Since the report of Bellman and colleagues (1997), many studies, including several randomized controlled trials, have evaluated omission of the nephrostomy tube postoperatively with placement of an internal ureteral stent. It is important to note that most of these studies patients were excluded if they had significant bleeding or perforation or if a second percutaneous procedure was anticipated.

A meta-analysis of tubeless percutaneous nephrolithotomies published in 2012 included nine randomized controlled trials involving 547 patients (Shen et al., 2012). The results were stratified into four groups with regard to postprocedure drainage: tubeless with internal ureteral stent, small nephrostomy tube (8 to 9 Fr), medium nephrostomy tube (16 to 18 Fr), and large nephrostomy tube (20 to 24 Fr). The meta-analysis demonstrated that hospital stay and postoperative pain were reduced in the tubeless group compared with the medium- and large-tube groups, but were similar in the tubeless and small-tube groups. There were no significant differences between the tubeless group and any of the nephrostomy tube groups with regard to fever/infection, transfusion, or operative time. In two earlier meta-analyses that combined the nephrostomy groups into two instead of three groups, 4 to 10 Fr versus 14 to 24 Fr (Yuan et al., 2015) and 8 to 9 Fr versus 14 to 26 Fr (Ni et al., 2011), shorter hospital stay and reduced postoperative pain were noted in the tubeless group even in comparison to the small nephrostomy group. Thus the preponderance of evidence suggests **that tubeless percutaneous nephrolithotomy leads to shorter hospital stay and reduced postoperative pain in comparison to the use of large postprocedure nephrostomy tubes but that these benefits are less certain in comparison to small nephrostomy tubes.** A subsequent meta-analysis (Xun et al., 2017) and one large multi-institutional matched case-control study involving 488 patients (Cormio et al., 2013b) have yielded similar results. The tubeless approach appears to be safe even when supracostal access is used (Duty et al., 2013; Jun-

Ou and Lojanapiwat, 2010; Shah et al., 2006b) and in the setting of bilateral simultaneous procedures (Gupta et al., 2003; Shah et al., 2005).

There are some disadvantages to using an internal ureteral stent as an alternative to a nephrostomy tube, however, including loss of the percutaneous tract for a secondary procedure and the cost, inconvenience, and discomfort associated with an internal ureteral stent that requires cystoscopic removal. The discomfort of the ureteral stent is significant; in two randomized trials that used the Wisconsin Stone Quality of Life (WiSQoL) questionnaire, participants managed with an internal ureteral stent reported poorer scores than did those with nephrostomy tubes (Jiang et al., 2017; Zhao et al., 2016). To obviate the need for cystoscopic removal of the ureteral stent, several groups have offered alternatives including insertion of an externalized ureteral stent or insertion of an internal stent with an attached string that exits out the flank. In both cases, the stent can then be removed before hospital discharge without an additional procedure. Goh and Wolf first reported in 1999 the use of an externalized ureteral stent (single pigtail) as an alternative to a postoperative nephrostomy tube (Goh and Wolf, 1999). Since then, there have been a number of reports of this option (Abou-Elela et al., 2007; Al-Ba'adani et al., 2008; Karami et al., 2007; Lojanapiwat et al., 2001; Rana and Mithani, 2007) including three randomized controlled trials, one comparing an externalized ureteral stent to a large-caliber nephrostomy tube, which suggested a benefit in terms of reduced narcotic use and length of hospital stay (Tefekli et al., 2007). A meta-analysis including 863 patients from five randomized trials and two other studies compared internal and external ureteral stents and revealed no difference between the two techniques except for more stent-related symptoms in the internal stent group (Chen et al., 2018). Shpall and colleagues (2007) described the modification of leaving the attached string on the stent and placing the stent “upside down” so that the string can exit the flank. They described removing the stent as an outpatient 3 and 12 days postoperatively, but since then, others have reported removing the stent at the bedside on the first postoperative day (Berkman et al., 2008). One randomized trial has confirmed the safety of this approach (with stent removal 10 to 14 days postoperatively), compared with postoperative nephrostomy tube (removed on the second or third postoperative day) (Agrawal et al., 2014). Use of a Polaris Loop stent (Boston Scientific, Marlborough, MA) placed “upside down” offers less resistance at the time of removal (Fig. 12.28).



Two loops of stent in renal pelvis and lower pole
Access sheath in lower pole

FIG. 12.28 Use of a Polaris Loop stent (Boston Scientific, Marlborough, MA) placed "upside down." An attached string is left exiting the flank, which allows removal of the stent without an additional procedure.

These modifications of nephrostomy tube omission avoid many of the disadvantages of an internal ureteral stent but still leave the problem of loss of access in case a secondary procedure is required. With improved endoscopes, better ancillary tools, and growing experience with percutaneous surgery, the need for secondary procedures is declining. In properly selected patients including those who do not need external drainage (e.g., pyonephrosis, significant bleeding, significant collecting system injury) and those who are unlikely to need a secondary procedure, omission of the postoperative nephrostomy tube appears to be safe and effective.

No Drainage Tube

More recently, the idea of a "totally tubeless" percutaneous renal surgery, omitting both the nephrostomy tube and ureteral catheter, has been reintroduced. This can be considered in selected patients with low-volume stones, atraumatic single access, and no hemorrhage, perforation, or obstruction. A meta-analysis of five randomized controlled trials and four nonrandomized comparative studies comparing "totally tubeless" percutaneous nephrolithotomy to percutaneous nephrolithotomy with a postprocedure nephrostomy tube suggests that the "totally tubeless" approach reduces hospital stay, analgesic requirement, and time to return to normal activity without increasing complications (Zhong et al., 2013). These outcomes have been mirrored in a single, small randomized controlled trial conducted in the pediatric population (Aghamir et al., 2012). Total health care expenditures are also decreased in the setting of a totally tubeless approach (Choi et al., 2014).

Tract Sealants.

One of the concerns with any approach that omits the nephrostomy tube after percutaneous renal surgery is that of hemorrhage from the tract. **Although the evidence from randomized controlled trials suggests that the size or presence of the nephrostomy tube does not affect the degree of postoperative bleeding, there is still a potential for dramatic bleeding after any percutaneous procedure—and such bleeding would be more problematic without a nephrostomy tube in place.** Several groups have described adjuncts intended to enhance hemostasis of the percutaneous tract including placing a fascial suture (Li et al., 2011), direct monopolar cauterization of the tract (Chang et al., 2011; Mouracade et al., 2008), cryotreatment of the tract (Okeke et al., 2009), and insertion/instillation of hemostatic agents into the tract including oxidized cellulose (Aghamir et al., 2006), gelatin sponge (Singh et al., 2008), gelatin granules plus thrombin (Lee et al., 2004; Li et al., 2011; Nagele et al., 2006), fibrin glue (Gudeman et al., 2012; Noller et al., 2004), collagen matrix coated with fibrin glue (Cormio et al., 2012), and temporary compression with nonabsorbable surgical gauze impregnated with kaolin (Koo et al., 2015). Randomized studies have failed to show an impact on postoperative bleeding with the use of tract-sealing agents, thus their utility in routine practice remains questionable (Aghamir et al., 2006; Cormio et al., 2012; Istanbulluoglu et al., 2013; Shah et al., 2006b; Singh et al., 2008; Wang et al., 2014; Yu et al., 2014; Ziaee et al., 2013).

Key Points: Postprocedural Nephrostomy Drainage

- The advantages of a postoperative nephrostomy tube include good drainage and control of the upper urinary tract and maintenance of percutaneous access for additional procedures. Inclusion of an extension down the ureter provides the greatest control and assurance of drainage.
- Small-caliber nephrostomy tubes are associated with less pain than large-caliber nephrostomy tubes and are not associated with any increased

hemorrhage.

- Use of a ureteral stent instead of a large-caliber nephrostomy tube is associated with reduced narcotic use and decreased length of hospitalization. The benefit of nephrostomy omission is less apparent when compared with a small-caliber nephrostomy tube. In properly selected patients, use of a ureteral stent instead of a nephrostomy tube does not affect stone-free or complication rates.
- Options for ureteral stenting without using a nephrostomy tube afterward include an internal ureteral stent that is removed cystoscopically, an internal ureteral stent that is removed by string exiting the flank, and an externalized ureteral stent that is removed along with the urethral catheter to which it is taped.
- After straightforward procedures with atraumatic single access and no hemorrhage, perforation, or obstruction, some patients can be managed without a nephrostomy tube or a ureteral stent.
- The utility of adjuncts for tract hemostasis is uncertain.

Training

Efforts to enhance training for percutaneous surgery of the upper urinary tract have focused on obtaining percutaneous access. Summarizing their own experience and other reports (Allen et al., 2005; Tanriverdi et al., 2007), de la Rosette and colleagues estimated that a trainee must perform approximately 24 percutaneous nephrolithotomies to attain proficiency, whereas competence is not achieved until the experience includes 60 cases, and excellence is not obtained until more than 100 cases have been performed (de la Rosette et al., 2008). Training during residency is the most effective way to develop the skills, but maintenance of skills requires ongoing experience. In a survey of urologists who completed a single-residency program, those trained in percutaneous access were more likely to perform percutaneous surgical procedures than those not trained in percutaneous access (92% vs. 33%). Of those who performed percutaneous surgery, urologists with training did more procedures than those without training (14.0 vs. 3.3 procedures annually). However, only about one third of respondents in both groups continued to attain their own percutaneous access (27% vs. 11%) (Lee et al., 2004).

The most advanced trainer is the PERC Mentor (Simbionix Ltd., Lod, Israel), a computer-assisted simulator for percutaneous access procedures guided by fluoroscopy (Fig. 12.29). The PERC Mentor has undergone preclinical validation, confirming that training on the PERC Mentor improves performance on the PERC Mentor (Knudsen et al., 2006; Zhang et al., 2013) and that trained individuals more proficiently attain percutaneous renal access in a porcine in-vivo model (Margulis et al., 2005), but validation of the impact on performance in the human operating room is lacking (Stern et al., 2007). Other novel trainers for percutaneous renal access includes one that incorporates simulated fluoroscopic imaging (Veneziano et al., 2015) and the use of patient-specific three-dimensional modeling of anatomy (Li et al., 2013a). At the least, these trainers can serve as an introduction for trainees by orienting them to the necessary anatomic considerations and familiarizing them with the physical movements of the procedure. It is unknown if these or other devices can be used to validate the skills of trainees and clinicians.

Special Situations

Horseshoe Kidney

Although antegrade access into horseshoe kidneys is somewhat different than into normal kidneys, standard techniques can generally still be used. CT or MRI should be considered for preoperative assessment of horseshoe kidneys, both to assess for the possibility of retro-renal colon (Skoog et al., 1985) and to assess the vasculature and relationship of the calyces to the anticipated puncture site. In a series of 12 patients undergoing percutaneous nephrolithotomy in horseshoe kidneys, 5 had bowel posterior to the kidney on CT (Al-Otaibi and Hosking, 1999). Horseshoe kidneys often have extra and eccentric calyces that can be difficult to access. In other ways, however, percutaneous access to a horseshoe kidney is more favorable than in normal kidneys. The anteroposterior tilt of the kidney is prominent, which makes the upper pole the most superficial and posterior aspect of the horseshoe kidney. In addition, the upper pole is usually inferior to the ribs. **Upper-pole access is useful in horseshoe kidneys because this is the easiest calyx to enter, the puncture rarely needs to be supracostal, and it provides excellent access to most of the kidney and the ureter because of alignment of the long axis of the moiety** (Fig. 12.30). The initial entry into a horseshoe kidney is more medial than in normal kidneys and can pass through the paraspinous musculature. The distance to the lower pole and ureter can be great in an obese or muscular patient, such that extra-long rigid nephroscopes or flexible nephroscopy may be necessary. In some cases, middle calyceal access is preferred because the upper pole is so far away from the pathology, but lower-pole calyces are usually not safely accessible with direct percutaneous puncture. The vasculature of horseshoe kidneys is aberrant, but vessels enter and exit the kidney in an anteromedial location (except for some at the isthmus), so direct vessel injury is rare with well-planned access (Janetschek and Kunzel, 1988). Overall, among a total of 309 percutaneous procedures (primarily nephrolithotomy) reported in horseshoe kidneys, there were 12 (3.9%) major hemorrhagic complications and only 1 (~0.3%) colon injury (Al-Otaibi and Hosking, 1999; Darabi Mahboub et al., 2007; Etemadian et al., 2013; Gupta et al., 2009; Lojanapiwat, 2005; Majidpour and Yousefinejad, 2008; Miller et al., 2008; Mousavi-Bahar et al., 2007; Purkait and Goel, 2015; Shokeir et al., 2004; Symons et al., 2008; Viola et al., 2007; Wu et al., 2014).

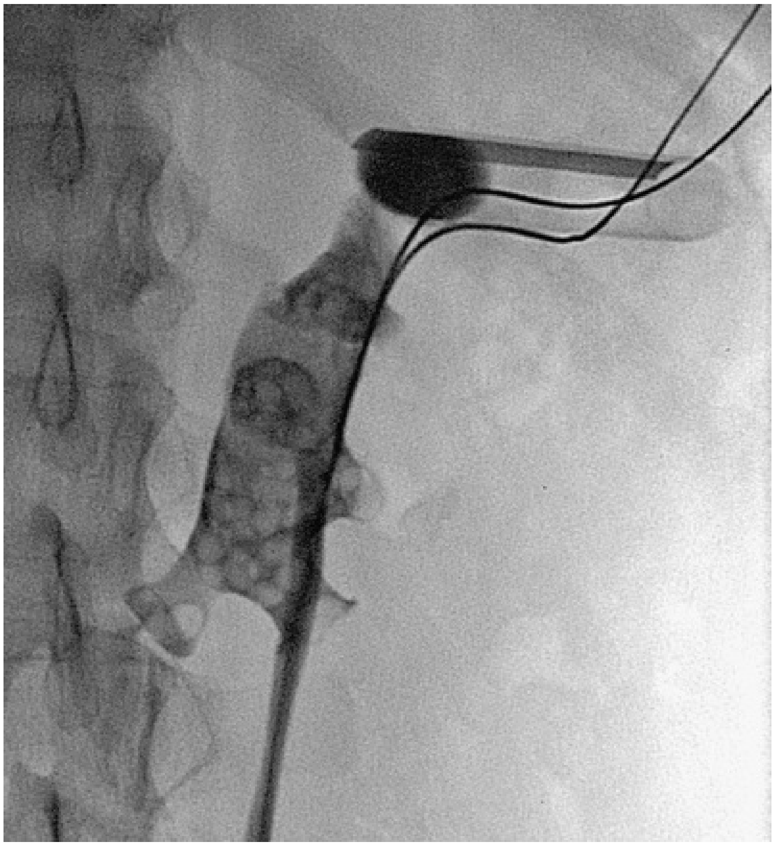

FIG. 12.30 Percutaneous access sheath (radiolucent except for a radiopaque stripe) in upper pole of horseshoe kidney. Note medially directed lower pole calyx. Although not apparent from this radiograph, the access site is subcostal.

Pelvic/Ectopic Kidney

Ectopic kidneys can range in location from the pelvis to the thorax. Pelvic kidneys are often difficult to access through a posterior approach, so supine positioning and transabdominal access may be necessary if permitted by overlying bowel. In some cases, advanced guidance techniques such as CT or MRI may be needed for safe access. Rarely, laparoscopic or robotic assistance may be required to mobilize overlying bowel such that the kidney can be safely punctured. In 12 series of laparoscopically directed antegrade percutaneous nephrolithotomy into pelvic kidneys published since 2001 that described a total of 35 patients, all procedures were reported to be successful and without complications (Aquil et al., 2006; Aron et al., 2005a; El-Kappany et al., 2007; Goel et al., 2006; Gupta et al., 2009; Maheshwari et al., 2004; Matlaga et al., 2006; Mousavi-Bahar et al., 2008; Santos et al., 2004; Tahmaz et al., 2009;

Tepeler et al., 2013; Troxel et al., 2002). As a simpler alternative to laparoscopic assistance, anterior percutaneous access into pelvic kidneys using a supine oblique position with a pad under the ipsilateral hemipelvis and using ultrasonography to assess for intervening bowel has been reported to be a safe technique in selected patients (Desai and Jasani, 2000; Mousavi-Bahar et al., 2007). If bone does not intervene between the appropriate calyx and the skin, then a posterior approach can be used just above the iliac bone (Atmaca et al., 2007) or through the greater sciatic foramen via a transgluteal approach (Mullins et al., 2015; Watterson et al., 2001).

Transplant Kidney

Approaching a transplant kidney percutaneously presents several challenges. First, retrograde access with a ureteral catheter is often challenging because of the anterior location of the ureteroneocystotomy and short ureteral length, which makes durable purchase with a guidewire difficult. When retrograde access cannot be achieved to facilitate contrast opacification of the collecting system, the initial puncture is best guided by ultrasound. In addition, the pelvic location of the transplant kidney almost always mandates an anterior approach with the patient in supine position. Fortunately, the extraperitoneal location of most renal transplants limits the likelihood of intervening bowel. Finally, there is typically a dense fibrosis surrounding the transplant kidney, which may be resistant to standard balloon tract dilation. In these cases, use of a fascial incising needle coupled with balloon dilation or use of telescoping metal dilators may be necessary. Of 81 percutaneous procedures in transplant kidneys reported in 11 series using ultrasonographically and/or fluoroscopically directed percutaneous access, all but six were technically successful, and there were no major complications (Challacombe et al., 2005; Francesca et al., 2002; Klingler et al., 2002; Krambeck et al., 2008b; Oliveira et al., 2011; Rifaioglu et al., 2008; Stravodimos et al., 2012; Verrier et al., 2012; Wyatt et al., 2009; Yuan et al., 2015).

Complications

Among more than 5000 patients undergoing percutaneous renal surgery, slightly more than 10% experienced major complications based on the modified Clavien-Dindo system (Labate et al., 2011).

Acute Hemorrhage

Acute hemorrhage is the most common significant complication of percutaneous access into the upper urinary tract collecting system. **Percutaneous nephrostomy alone results in hemorrhage requiring transfusion in 0.5% to 4% of procedures** (ACR, 2007; Radecka and Magnusson, 2004; Rana et al., 2007; Wah et al., 2004)**. With the addition of percutaneous nephrolithotomy, likely caused by the larger caliber of the percutaneous tract and increased intrarenal manipulation, the incidence of hemorrhage requiring blood transfusion rises to 0.8% to 20% depending on what series is reviewed** (Akman et al., 2011; Chew et al., 2009; Duvdevani et al., 2007; Kamphuis et al., 2015; Keoghane et al., 2012; Kukreja et al., 2004; Labate et al., 2011; Muslumanoglu et al., 2006; Netto et al., 2005; Preminger et al., 2005; Tomaszewski et al., 2010b). **Factors associated with hemorrhage during percutaneous renal surgery include patient characteristics, multiple access sites, supracostal access, increasing tract size, tract dilation with methods other than balloon dilation, prolonged operative time, and renal pelvic perforation** (Akman et al., 2011; Hegarty and Desai, 2006; Keoghane et al., 2012; Kukreja et al., 2004; Lee et al., 2013; Martin et al., 1999; Netto et al., 2005; Rastinehad et al., 2009; Stoller et al., 1994).

Most hemorrhage occurs from the renal parenchyma, and in most cases this hemorrhage is not significant. Parenchymal bleeding is minimized by proper entry and dilation and by careful manipulation of the sheath. **The access sheath provides intraoperative tamponade of parenchymal bleeding. Postoperatively, hemostasis is achieved by collapse of the parenchyma onto itself.** Unless the postoperative nephrostomy tube is as large as or larger than the sheath used during the procedure, it likely does not contribute to hemostasis. There is no difference in measures of postoperative bleeding between small (8- to 18-Fr) and large (20- to 28-Fr) tubes (Desai et al., 2004; De Sio et al., 2011; Liatsikos et al., 2002; Maheshwari et al., 2000; Marcovich et al., 2004; Pietrow et al., 2003), and some work suggests less postoperative bleeding with smaller-caliber nephrostomy tubes (Cormio et al., 2013a). In fact, hemorrhage is no greater when the nephrostomy tube is omitted altogether (Shen et al., 2012). **If there is noticeable bleeding from the tract after sheath removal following an otherwise unremarkable procedure, this suggests bleeding from intraparenchymal vessels.** Hemostatic maneuvers such as cauterization or placement of hemostatic material can be considered**, but in general the best management is to insert and occlude a nephrostomy tube, apply pressure to**

the incision, and let the collecting system clot off. A tubeless approach is not advised in such cases because maintenance of percutaneous access to the upper tract might facilitate management. Nephrostomy tubes should not be irrigated the day or evening of the procedure if they are not draining; it is best to let the collecting system remain occluded to tamponade bleeding. By the next morning, it is safe to gently irrigate the tube because hemostasis is more certain.

If the procedure was not complicated by bleeding but severe hemorrhage occurs after sheath removal and is refractory to the hemostatic measures described earlier, then use of a Kaye Nephrostomy Tamponade Balloon (Cook Urological, Spencer, IN) should be considered. This is a nephrostomy tube surrounded by a balloon (Fig. 12.31) (Kaye and Clayman, 1986), which is inflated up to 36 Fr to tamponade the parenchymal bleeding just as the sheath did intraoperatively. This device should be removed under fluoroscopic guidance with guidewire access down the ureter in case tube reinsertion is required for recurrent bleeding.

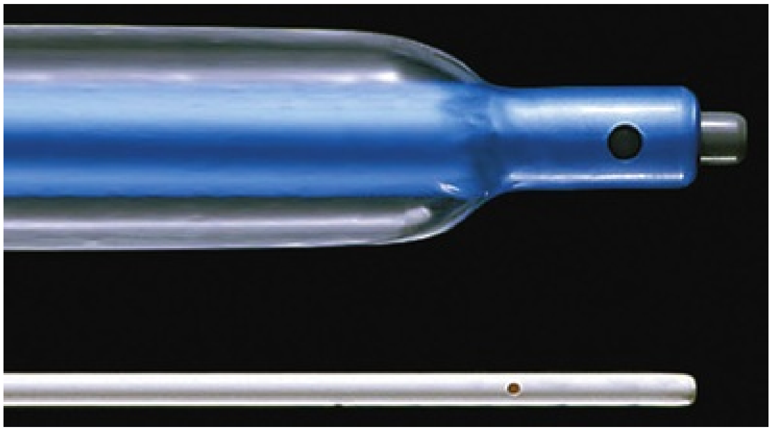

FIG. 12.31 Kaye Nephrostomy Tamponade Balloon.

Intraoperative hemorrhage from an injured vein or artery within the collecting system mandates cessation of the procedure if vision is lost. In most cases, especially if the injury appears to be venous, then placing a nephrostomy tube and letting the collecting system clot off is effective. If this is not effective, then Gupta and colleagues (2002) have described inserting a Council catheter as a nephrostomy tube, with the balloon inflated slowly at the site where contrast material enters into the venous system until repeated nephrostography reveals no more extravasation of contrast material. A hole should be cut into the tube proximal to the balloon to provide drainage of calyces obstructed by the balloon. Millard and associates (2010) have reported an addition to this technique, in which gelatin matrix hemostatic sealant is injected into the tract peripheral to the balloon occluding the renal injury and then a second catheter is inserted with the balloon placed just underneath the skin surface, such that the tract is occluded and the gelatin matrix hemostatic sealant contributes to hemostasis. Another alternative, described in one case of a large venous injury, is to place a large-bore catheter through the injury site into the main renal vein and then back it out several days later (Shah et al., 2005). A small arterial injury can sometimes be addressed with fulguration under direct vision, but if this is not successful and bleeding does not cease with pressure, or in cases of significant arterial hemorrhage, then selective angioembolization will likely be required (see later).

Delayed Hemorrhage

Postoperative hemorrhage can occur with the nephrostomy tube in place, at time of tube removal, or after discharge from the hospital. **Less than 1% of major percutaneous procedures are complicated by delayed hemorrhage requiring treatment** (El Tayeb et al., 2015; Keoghane et al., 2012; Kessaris et al., 1995; Martin et al., 2000; Richstone et al., 2008; Tomaszewski et al., 2010b). **Delayed hemorrhage is usually caused by arteriovenous fistulas or arterial pseudoaneurysms, with the latter being more common.** Arteriovenous fistulas occur when a paired set of artery and vein are injured, and arterial blood enters directly into the vein (Fig. 12.32). The weak vein wall cannot sustain the high arterial pressure and ruptures. An arterial pseudoaneurysm occurs when an artery is injured, clots off, and then intermittently ruptures, often clotting off again at variable intervals (Fig. 12.33A). Any report of bright-red blood in the urine or nephrostomy tube after surgery should raise clinical suspicion for either of these entities. In most instances, bleeding occurs approximately 1 week after surgery (El Tayeb et al., 2015). The patient may complain of flank pain associated with hematuria if the bleeding is associated with clot formation, which can cause obstruction and mimic renal colic. Cases of suspected arteriovenous fistula or pseudoaneurysm should be promptly evaluated with angiography, which is diagnostic in more than 90% of cases and allows for subsequent treatment in the same setting in most instances (Richstone et al., 2008). Both arteriovenous fistulae and pseudoaneurysms are treated with selective angioembolization, which is usually effective (Jain et al., 2009; Ji et al., 2012; Martin et al., 2000; Patterson et al., 1985; Richstone et al., 2008). Nonetheless, in one multicenter study embolization failure (occurring in 10% of cases), was more common in patients with multiple percutaneous access sites, more than two bleeding sites on angiography, and when gelatin only was used as the embolic material (Zeng et al., 2013). Moreover, angioembolization can be associated with partial or total renal loss if it is not selective enough (Fig. 12.33B). An alternative is placement of a covered stent to occlude the site of arterial injury, which has the benefit of preserving downstream renal parenchyma because renal blood flow is preserved (Areste et al., 2005; Sprouse and Hamilton, 2002).

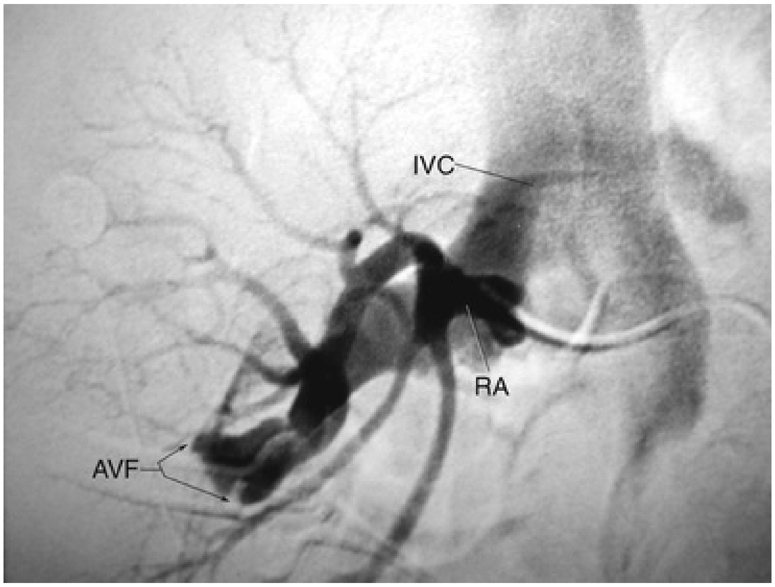

FIG. 12.32 Angiography of the renal artery *(RA)* is followed promptly by contrast material appearing in the inferior vena cava *(IVC),* suggesting the presence of an arteriovenous fistula *(AVF).*

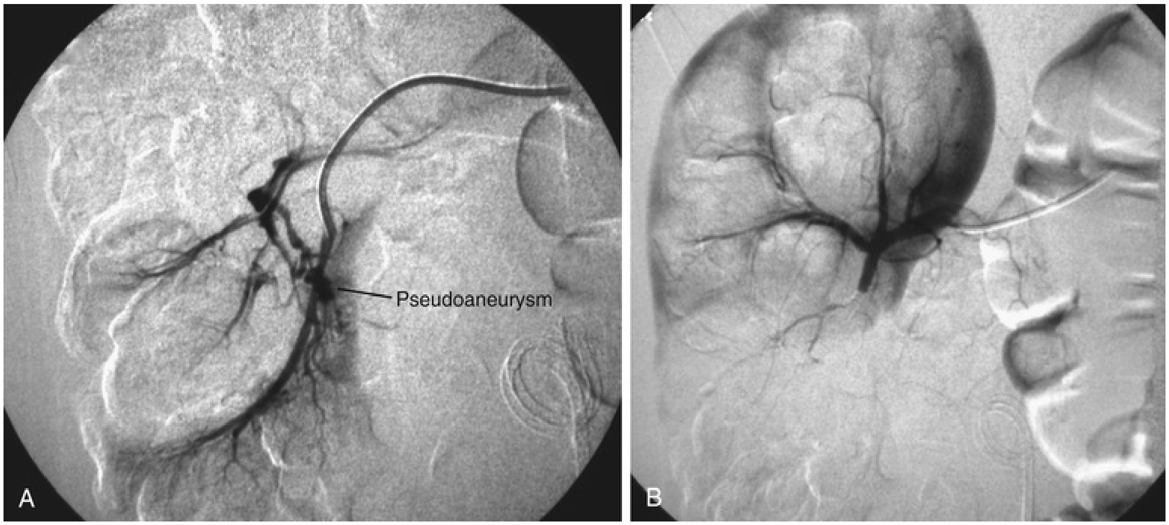

FIG. 12.33 (A) Angiography demonstrates a pseudoaneurysm in the lower pole of the right kidney. (B) Angioembolization was successful at occluding the pseudoaneurysm, but it also devascularized a large portion of the lower pole.

Collecting System Injury

Tears in the infundibulum are not uncommon during percutaneous surgery of the upper urinary tract collecting system. They generally do not cause problems intraoperatively as long as there is no hemorrhage. Ureteral injuries are rare but can occur as a result of inflating the ureteral balloon occlusion catheter in the ureter or during other ureteral manipulation. These injuries generally will heal over a ureteral stent. Renal pelvic perforation can occur during initial access or during dilation. Pushing on a renal pelvic stone too hard during lithotripsy or misusing a lithotripter or resectoscope can also perforate the renal pelvis. **Renal pelvic perforation is usually recognized intraoperatively** (Fig. 12.34). **Collapse of a previously distended renal pelvis is a usual sign if the perforation is not visualized directly at first.** A perforation that has not been recognized intraoperatively might be heralded by postoperative abdominal distention, ileus, and/or fever. **If noted intraoperatively, abort the procedure unless it is near completion, in which case the task can be completed at lower irrigation pressure if the patient is doing well clinically. At the completion of a case in which renal pelvic perforation has been noted, insert a nephroureteral stent or a nephrostomy tube plus an internal ureteral stent to optimize drainage, and then wait 2 to 7 days before nephrostography and tube removal, depending on the severity of the injury.** If renal pelvic perforation is detected postprocedure despite adequate drainage of the collecting system, then placement of a percutaneous drain into the urinoma might be required. There have been reports of massive intra-abdominal collection of extravasated fluid after percutaneous renal surgery (Etemadian et al., 2012; Ghai et al., 2003; Peterson et al., 1985; Pugach et al., 1999).

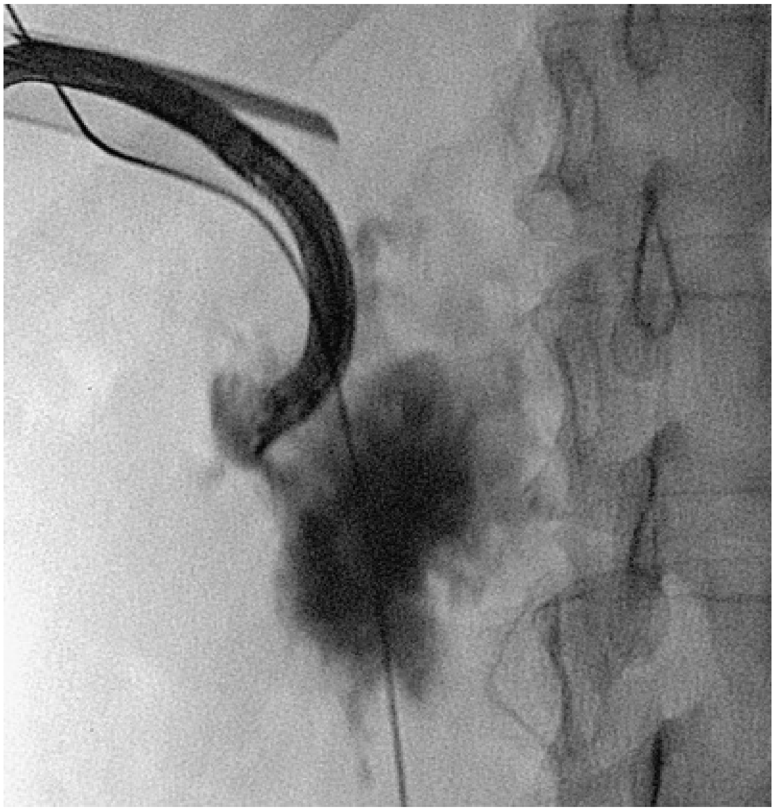

FIG. 12.34 Renal pelvic perforation confirmed with injection of contrast material through flexible nephroscope.

Visceral Injury

Any abdominal organ close to the kidney can be injured during percutaneous renal surgery including the colon, duodenum, jejunum, spleen, liver, and biliary system. Thankfully, injury to adjacent viscera at the time of percutaneous renal access or surgery is exceedingly rare. **Two recent large studies including more than 16,000 patients undergoing percutaneous nephrolithotomy indicate the incidence of colon injury to be around 0.1%** (AslZare et al., 2014; Kachrilas et al., 2012). **As would be expected on the basis of the anatomy, with the apposition of the colon to the kidney being greatest on the left side and at**

the lower pole, the left colon is injured twice as often as the right colon, and the majority of colon injuries involve access to the lower pole (El-Nahas et al., 2006). Additional risk factors include advanced patient age, dilated colon, prior colon surgery or disease, thin body habitus, and the presence of a horseshoe kidney (El-Nahas et al., 2006; Goswami et al., 2001; Korkes et al., 2009; Michel et al., 2007). Injury might be less likely with the patient in the supine position; one study reported a retrorenal colon on CT in 1.9% of patients in the supine position versus 10% in prone patients (Hopper et al., 1987). An additional study based on CT-measured distance from a hypothetical puncture location to the colon favored supine versus prone positioning (Desoky et al., 2018).

Intraoperative detection of colonic injury confers easier management. If not determined intraoperatively, colon injury should be considered postoperatively if a patient develops unexplained fever, prolonged ileus, unexplained leukocytosis, rectal bleeding, evidence of peritoneal inflammation, or fecaluria or pneumouria. Clinically apparent nephrocolonic fistula may be the presenting sign, or the injury may not be noted until the time of postoperative nephrostogram. **Most colon injuries are extraperitoneal and can be managed conservatively** (El-Nahas et al., 2006; Gerspach et al., 1997; Goger et al., 2012; Kachrilas et al., 2012; Korkes et al., 2009; Traxer, 2009). **The traditional principle of care is prompt and separate drainage of the colon and urinary collecting system,** although some authors report that internal urinary tract drainage alone is adequate (Maghsoudi et al, 2017). Give nothing by mouth for a few days, and then start clear liquids and advance diet as tolerated. If the injury is intraperitoneal, or if the patient develops peritonitis or sepsis, then open surgical repair may be required.

Small bowel injuries are even less common than colonic injury, described in only a few cases reports (Ahmed and Reeve, 1995; Al-Assiri et al., 2005; Culkin et al., 1985; Lopes-Neto et al., 2000; Morris et al., 1991; Kumar et al., 1994; Ricciardi et al., 2007; Santiago et al., 1998; Traxer, 2009; Winer et al., 2009). Detection is by clinical signs and symptoms of peritonitis or by noting a nephroenteric fistula during postoperative nephrostography. Although open surgery may be required, conservative management using percutaneous intraduodenal catheterization or simple nasogastric or nasoduodenal drainage, combined with drainage of the upper urinary tract, fasting, and parenteral feeding, has been successful.

Studies based on CT and MRI have suggested that splenic and hepatic injuries should be unlikely unless the kidney is accessed above the 10th rib,

although access above the 11th or 12th rib might traverse these organs in rare cases (Hopper and Yakes, 1990; Robert et al., 1999). These relationships change when splenomegaly or hepatomegaly is present, and access guided by CT is recommended. Splenic or hepatic injuries to orthotopic and normal-sized organs occur almost exclusively with supracostal upper-pole renal access. Splenic injury can often be managed conservatively with careful serial abdominal examinations and complete blood count measurement (Carey et al., 2006; Desai et al., 2010; Goldberg et al., 1989; Santiago et al., 1998; Schaeffer et al., 2008; Thomas et al., 2009), but it rarely requires laparotomy and potentially splenectomy because of hemorrhage (Kondas et al., 1994; Shah et al., 2007). Liver injury is less likely to be associated with significant hemorrhage—indeed the liver can be traversed percutaneously to obtain biliary access (Nadler et al., 2002), and purposeful transhepatic percutaneous renal surgery has been reported (Matlaga et al., 2006). As such, liver injuries during percutaneous renal surgery can be managed conservatively (El-Nahas et al., 2008).

There have been a few reported cases of biliary peritonitis caused by injury of the gallbladder or biliary tree, which require exploratory laparotomy/laparoscopy and cholecystectomy because of the high mortality rate of bile peritonitis (Fisher et al., 2004; Kontothanassis and Bissas, 1997; Martin et al., 1996; Patel and Nakada, 2010; Ricciardi et al., 2007; Saxby, 1996). Postoperative pancreatitis, without evidence of direct pancreatic injury, has been described as well (Chitale et al., 2005).

Pleural Injury

Hydrothorax, and occasionally pneumothorax, is a risk for percutaneous access to the upper urinary tract–collecting system. Supracostal access is the main risk factor; access below the 12th rib rarely results in hydrothorax or pneumothorax (Lojanapiwat and Prasopsuk, 2006; Maheshwari et al., 2009; Munver et al., 2001; Radecka et al., 2003). The incidence of pleural complications with punctures above the 12th rib (the 11th intercostal space) is generally considered an acceptable risk if that approach provides optimal access to the upper urinary tract. Access above the 11th rib or higher carries a much greater risk for pleural injury. **Among 16 reports that distinguished between access above the 12th rib and access above the 11th rib, reporting a total of 1384 supracostal percutaneous accesses, the incidence of hydrothorax/pneumothorax that required intervention varied from 0% to 18% for access superior to the 12th rib (weighted mean of 4.6%) and from**

0% to 100% for access superior to the 11th rib (weighted mean of 24.6%) (Aron et al., 2005b; Golijanin et al., 1998; Gupta et al., 2002; Kekre et al., 2001; Lojanapiwat and Prasopsuk, 2006; Munver et al., 2001; Muzrakchi et al., 2003; Narasimham et al., 1991; Picus et al., 1986; Radecka et al., 2003; Shaban et al., 2008; Sukumar et al., 2008; Wong and Leveillee, 2002; Yadav et al., 2006; Yadav et al., 2008; Young et al., 1985).

Nephropleural fistula (urinothorax) is a direct and persistent communication between the intrarenal collecting system and the intrathoracic cavity (Handa et al., 2007; Ray et al., 2003; Shleyfer et al., 2006). It can follow percutaneous renal access of the upper urinary tract in the setting of pleural transgression. Some degree of distal ureteral obstruction usually contributes to the problem. Most commonly, nephropleural fistula is diagnosed after the percutaneous tube is removed, but it can occur in the setting of a recognized hydrothorax when the persistent communication is documented on nephrostography at the time of intended tube removal. Lallas and colleagues (2004) reported that nephropleural fistula never occurred in association with subcostal access but did complicate 2.3% of punctures superior to the 12th rib and 6.3% of punctures superior to the 11th rib.

Pleural complications of supracostal percutaneous access can often be detected with chest fluoroscopy during or at the conclusion of the procedure. Fluid can be seen tracking along the lateral borders of the chest cavity and compressing the ipsilateral lung. Although postoperative chest radiography is more sensitive than intraoperative fluoroscopy, some authors report that thoracostomy was never required on the basis of postoperative chest radiography when intraoperative chest fluoroscopy was negative (Bjurlin et al., 2012; Ogan et al., 2003).

Thoracostomy is not necessary for all patients with hydrothorax. If hydrothorax is noted intraoperatively, then insert a small-caliber (8-Fr to 12-Fr) Cope nephrostomy tube as the thoracostomy (Fig. 12.35), using fluoroscopic guidance and the same general techniques as for antegrade percutaneous renal access (Ogan and Pearle, 2002). A Heimlich valve, rather than water seal drainage, is all that is necessary in the absence of lung injury. If a hydrothorax is noted on the postoperative chest radiograph, then place a small-caliber tube only if the effusion is large or there is evidence of respiratory compromise or hemodynamic instability. A large-bore thoracostomy tube as for lung injury is rarely required.

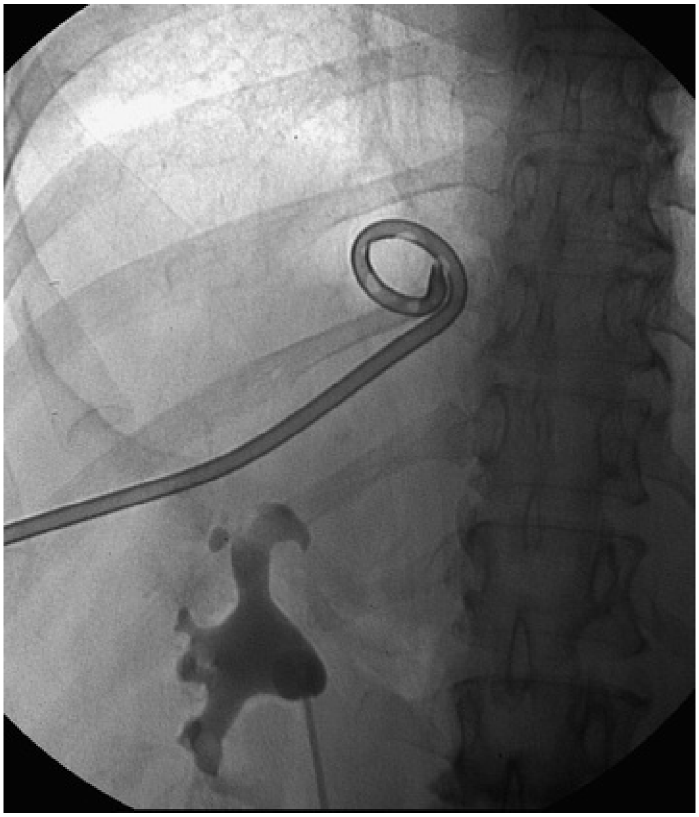

FIG. 12.35 A 12-Fr Cope catheter placed into the chest when a large hydrothorax was noted intraoperatively on fluoroscopy.

Metabolic and Physiologic Complications

Normal saline should be the irrigant for percutaneous renal surgery, with the exception of glycine or similar nonelectrolytic isotonic fluids when monopolar electrocautery is used. Irrigation with water during percutaneous renal surgery risks intravascular hemolysis, which can be fatal. At least one death associated with water irrigation during percutaneous nephrolithotomy has been described (Bennett et al., 1984), and the author is aware of an unreported case. Intravascular or extravascular extravasation of nonelectrolytic isotonic fluid from continued irrigation in the setting of a large venous injury or collecting system perforation, respectively, can result in hyponatremia and other electrolyte abnormalities, renal or hepatic dysfunction, and mental status changes. When normal saline is used in uncomplicated cases, the amount of fluid absorption is generally clinically insignificant (Köroğlu et al., 2003; Kukreja et al., 2002), although in one study 28% of patients absorbed more than 1 liter (Malhotra et al., 2001). A large amount of saline extravasation can lead to clinically significant respiratory distress or cardiac failure caused by volume overload.

Venous gas embolism is a rare but potentially fatal complication of percutaneous renal surgery. The gas (in this case, air) enters the venous system and passes through the right heart into the pulmonary circulation, blocking the output of the right heart, which results in hypoxemia, hypercapnia, and depressed cardiac output. Gas can also pass through a patent foramen ovale to enter the arterial system, which can result in neurologic deficits. Among six reported cases of venous gas embolism in association with percutaneous renal surgery, three were associated with air pyelography in combination with percutaneous access of the kidney (Cadeddu et al., 1997; Droghetti et al., 2002; Miller et al., 1984), one involved percutaneous surgery without air pyelography (Turillazzi et al., 2009), and two occurred after retrograde injection of air into the renal pelvis but before percutaneous puncture (Song et al., 2007; Varkarakis et al., 2003). Venous gas embolism is indicated by hypoxemia, evidence of pulmonary edema, increased airway pressure, hypotension, jugular venous distention, facial plethora, dysrhythmias, and auscultation of a mill-wheel cardiac murmur and/or the appearance of a widened QRS complex with right heart strain patterns on electrocardiography. The most sensitive measure is a sudden decrease in capnometry reading of the P(end-tidal)CO_2. Swift response is required and includes rapid ventilation with 100% oxygen, positioning the patient head down with the right side up, and general resuscitative maneuvers.

Postoperative Fever and Sepsis

After percutaneous nephrolithotomy, 15% to 30% of patients have a fever. Risk factors for fever/infectious complications after percutaneous nephrolithotomy include diabetes mellitus, paraplegia, indwelling ureteral stent or nephrostomy tube, prior percutaneous nephrolithotomy, multiple access tracts, infection stone, staghorn stone, positive preoperative urine culture, larger stones, and hydronephrosis (Aghdas et al., 2006; Charton et al., 1986; Draga et al., 2009; Gutierrez et al., 2013; Korets et al., 2011; Kumar et al., 2012; Lojanapiwat and Kitirattrakarn, 2011; Rivera et al., 2016; Troxel and Low, 2002). **Most patients with fever after percutaneous nephrolithotomy, assuming appropriate antimicrobial prophylaxis, do not have infection** (Cadeddu et al., 1998). Rather, the majority suffer from systemic inflammatory response syndrome (SIRS), a nonspecific immune response defined by hyperthermia/hypothermia, leukocytosis/leukopenia, tachycardia, and tachypnea, which can be caused by either infectious or noninfectious insults**.** Self-limited fever after percutaneous interventions without associated hemodynamic compromise can often be managed expectantly. Indeed, most patients in this setting can be routinely discharged without intervention or risk for unplanned readmission (Moses et al., 2017).

Sepsis, differentiated from SIRS alone in that an identifiable infectious source (i.e., positive urine or blood culture) can be identified, occurs in 0.5% to 2.5% of patients after percutaneous nephrolithotomy (Dogan et al., 2007; Duvdevani et al., 2007; Gonen et al., 2008b; Labate et al., 2011; Li et al., 2013b; Lojanapiwat and Kitirattrakarn, 2011; Seitz et al., 2012). Positive preoperative urine cultures should be treated. Even if bacteriologic cure is not possible (e.g., infectious stone, indwelling nephrostomy tube), bacterial counts should be suppressed as much as possible to reduce the risk for infectious complications. Nonetheless, a negative urine culture does not guarantee against sepsis because the voided urine culture may not reflect the intrarenal urine (Korets et al., 2011; Lojanapiwat and Kitirattrakarn, 2011; Mariappan et al., 2005; Rao et al., 1991). **If pus is aspirated upon initial percutaneous entry to the upper urinary tract, the safest measure is to abort the procedure and leave a nephrostomy tube for drainage.**

Neuromusculoskeletal Complications

Prone positioning for percutaneous renal surgery has the potential for a number of neuromusculoskeletal injuries (Edgcombe et al., 2008; Shermak et al., 2006). **Excessive pressure on neural and vascular structures, whether directly from the operative table or indirectly through the positioning of limbs, may lead to short- or long-term disability.** Most reported injuries associated with prone positioning are related to the head and neck region including ocular injury resulting in visual loss, facial nerve injury or necrosis over facial bones or the tip of the nose, and cerebrovascular accident caused by carotid or vertebrobasilar artery dissection. Careful padding of the head, in a neutral and nonextended position, is important. Malpositioning of the extremities can lead to peripheral nerve injury (Winfree and Kline, 2005). The shoulder and elbow should not be abducted more than 90 degrees, to prevent brachial plexopathy, and generous padding at the elbow and forearm reduces the risk for nerve compression. Knees need to be padded. Ankles should be elevated to reduce pressure on the dorsum of the foot.

Venous Thromboembolism

The incidence of venous thromboembolism with percutaneous renal surgery is low (<3% in older series of percutaneous nephrolithotomy) (Lee et al., 1987; Segura et al., 1985), but there are no recent data. **The American Urological Association's Best Practice Statement for the prevention of deep vein thrombosis in patients undergoing urologic surgery does not include percutaneous renal surgery among procedures for which prophylaxis against venous thromboembolism is recommended** (Forrest et al., 2009). Early ambulation is the best measure to reduce the already low risk for venous thromboembolism.

Collecting System Obstruction

Transient ureteral obstruction caused by ureteral edema or blood clot occurs commonly. To assess for this, nephrostomy tubes should be removed after nephrostography or after a period of clamping to assess clinically for distal ureteral obstruction. Much more uncommon is stricture formation, which can occur in the ureter, at the ureteropelvic junction, or in an infundibulum. If the stricture occurs early in the postprocedure course, then a nephrocutaneous fistula will develop. If it develops late, then hydronephrosis or hydrocalyx will occur. **In one large series, there was a 2% rate of infundibular stenosis after percutaneous nephrolithotomy** (Parsons et al., 2002). The obstructions developed in the areas that had been accessed percutaneously. Predisposing factors in this and other smaller reports (Ballanger et al., 1987; Buchholz, 2001; Weir and Honey, 1999) include large stone burden requiring multiple or long procedures and prolonged nephrostomy tube drainage, previous open stone surgery, diabetes mellitus, and obesity. The ureter (Culkin et al., 1987; Lopes-Neto et al., 2008) and the ureteropelvic junction (Ben Slama et al., 2005; Green et al., 1987) are smaller in caliber than the intrarenal collecting system and are therefore also susceptible to trauma.

Obstruction after percutaneous renal surgery should respond to endoscopic treatment in most cases, but open surgical reconstruction or excision with partial nephrectomy or total nephrectomy may be required.

Loss of Renal Function

Despite the direct puncture of renal parenchyma and enlargement of sometimes multiple tracts to up to 34 Fr, the kidney suffers little permanent damage after uncomplicated percutaneous renal surgery. Renal function does decrease slightly immediately after percutaneous renal surgery, reaching a nadir 48 hours postprocedure (Nouralizadeh et al., 2011), but long-term there is negligible loss of function (Chen et al., 1992; Ekelund et al., 1986; Kilic et al., 2006; Saxby, 1997), and in one study there appeared to be less damage to the kidney after percutaneous nephrolithotomy than after shock-wave lithotripsy (LeChevallier et al., 1993). In the setting of impaired function, especially caused by obstructing calculi, percutaneous surgery will often improve renal function (Bilen et al., 2008; Chandhoke et al., 1992; Chatham et al., 2002). Percutaneous renal surgery also causes no significant change in function of solitary kidneys (Canes et al., 2009; Jones et al., 1991; Liou and Streem, 2001). In one study of patients surveyed a mean of 19 years after treatment, there was no difference between shock-wave lithotripsy and percutaneous nephrolithotomy in the development of renal insufficiency or hypertension (Krambeck et al., 2008a).

When there is renal loss after percutaneous renal surgery, it usually is a result of disastrous vascular injury or the angioembolization used to treat hemorrhage.

Death

Death after percutaneous renal surgery is extremely rare, and when it occurs it is usually caused by underlying cardiovascular conditions (Labate et al., 2011; Seitz et al., 2012).

Key Points: Complications of Percutaneous Renal Access

- Patients should be clearly counseled before any percutaneous renal intervention regarding possible complications of the procedure.
- The most common complications after percutaneous renal access are bleeding and infection.
- Pleural injury or parenchymal lung injury is uncommon after percutaneous renal access but increases with supracostal punctures.
- Solid visceral injury is uncommon. Hepatic and splenic injury can often be managed conservatively. Injury to the small or large bowel requires prompt recognition and separation of renal and bowel drainage. Laparotomy may

be required in severe cases.

- Death after percutaneous renal access is exceedingly uncommon.

Retrograde Renal Access and Drainage

History

Although interest in ureteral catheterization has been documented for centuries, it was not until the development of the first cystoscopes that modern ureteral catheterization was possible. The first reported successful ureteral catheterization came in 1893 when Dr. James Brown, the head of the department of urology at Johns Hopkins, introduced a small catheter into each ureteral orifice for urine sampling in a paraplegic patient with persistent pyuria (Arcadi, 1999). It was not until the 1930s and 1940s and the development of pliable plastics that stents were manufactured that combined flexibility with sufficient rigidity. In the ensuing decades, a variety of reports indicate use of ureteral stents for ureteral injuries and malignant ureteral obstruction (Tulloch, 1952; Zimskind et al., 1967). Early stent design did not allow for stent retention, thus migration was a common problem. This was first addressed in 1974 with a self-retaining “Gibbons stent,” which featured sharp barbs along its length to prevent migration. The design was imperfect, however, and the stent itself was quite large at 11 Fr, thus limiting its use (Gibbons et al., 1974). The first double pigtail, self-retaining ureteral stent was developed in 1978 and serves as the predecessor to most commonly available modern ureteral stents used today (Finney, 1978).

Indications

The indications for retrograde renal drainage are vast, and roughly parallel those for percutaneous renal drainage (i.e., for renal obstruction). In addition, stents are often placed after routine ureteroscopy for stone disease. Drainage via ureteral stent placement is also important after a multitude of reconstructive surgeries to allow for ureteral healing, though these indications are beyond the scope of this chapter and are discussed elsewhere in this text. Specific scenarios in which retrograde versus antegrade renal drainage are preferred are outlined earlier in this chapter.

Surgical Technique

Before retrograde renal drainage, obtain urinalysis to evaluate for pyuria, and treat any infection before intervention. The AUA Guidelines recommend antibiotic prophylaxis in all patients undergoing cystoscopy with ureteral instrumentation (Wolf et al., 2008). Choice of anesthesia is dependent on the indication for which ureteral stent placement is being considered. Although ureteral stent placement can be performed in the awake patient with only local anesthesia (Sivalingam et al., 2013), in most cases, general anesthesia or sedation is preferable. Dorsal lithotomy position affords the surgeon ready access to the external genitalia and perineum and facilitates cystoscopy, although positioning can be modified to account for patient factors. A ureteral catheter introduced through the working channel of the cystoscope is used to intubate the ureteral orifice, with or without a leading guidewire. Retrograde pyelography delineates the ureteral and collecting system anatomy.

Guidewire Placement

There are numerous types of ureteral catheters and guidewires for ureteral stent placement. In most cases, a straight, open-ended ureteral catheter, typically 5 or 6 Fr, is used to stabilize and introduce a working guidewire. In challenging cases, the surgeon may choose an angled tip or torque stabilized angiographic catheter to further facilitate guidewire placement. Initial choice of guidewire is based on surgeon experience and preference. Guidewires for retrograde ureteral access have straight or curved tips and are available in a variety of materials such as PTFE, hydrophilic coated nitinol, or hybrid wires composed of a hydrophilic nitinol tip and PTFE body. Guidewires also vary in their stiffness, ranging from standard to stiff to super-stiff. Regardless of the guidewire chosen, the first objective is to successfully place the wire into the renal collecting system.

Stent Placement

The ureteral stent should be passed in a coaxial fashion over the working wire and into the renal collecting system. This can be accomplished by placement through the cystoscope working channel under direct vision using the supplied pusher. While monitoring the progress of the distal end of the stent in the bladder under direct vision, the proximal extent of the stent can be monitored using fluoroscopy until satisfied with the position. At this point, the guidewire is slowly removed to allow the proximal renal curl to form. The cystoscope is then positioned at the bladder neck, and the pusher is advanced until it is just within the field of view. The wire can then be completely withdrawn, which facilitates distal stent curl formation in the bladder. Advantages of stent placement under direct vision are the ability to monitor the distal extent of stent advancement to avoid overpassing the stent up the ureter and to potentially decrease fluoroscopy use. In addition, the added stability of a cystoscope is beneficial in settings in which stent passage may be challenging such as ureteral stricture or impacted stone, where the stent may otherwise tend to buckle rather than advance. Alternatively, the ureteral stent can be placed using fluoroscopic guidance only. In this situation, the cystoscope is removed and the pusher is used to advance the stent directly over the guidewire (Fig. 12.36A). It is typically best to position the fluoroscope over the pubic symphysis and monitor the radiopaque marker at the distal tip of the pusher (see Fig. 12.36B). Once this marker has been positioned at the mid-symphysis, the fluoroscope can be positioned over the ipsilateral renal location and the guidewire removed partially to form the proximal renal curl. After confirming good proximal position, the fluoroscope is repositioned over the pubic symphysis and the guidewire is completely withdrawn to form the distal curl of the stent (see Fig. 12.36C).

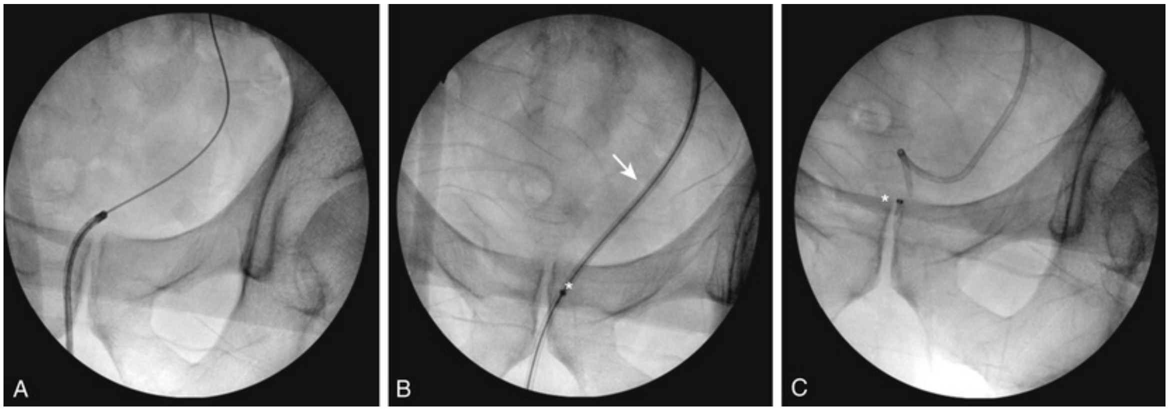

FIG. 12.36 (A) Cystoscope in bladder plus guidewire in ureter. (B) Stent placed in ureter through 10-Fr sheath (*asterisk* indicates radiopaque marker of pusher; *arrow* indicates 10-Fr sheath). (C) Guidewire and 10-Fr sheath removed; distal stent section coiled in bladder.

Stent Varieties

Materials

Most ureteral stents are composed of flexible polymers such as polyurethane, silicone, or others. In an effort to increase resistance to radial compression, such as in cases of malignant ureteral obstruction, metallic stents are available. The Wallstent is a self-expandable, metallic stent first developed for the management of extrinsic ureteral obstruction and refractory ureteral strictures (Pauer and Lugmayr, 1992; Reinberg et al., 1994). Though it does exhibit substantial resistance to compressive forces, the tendency for ureteral tissue ingrowth causing obstruction requiring ancillary endoscopic procedures has limited its widespread use (Lang et al., 2013). The Resonance stent (Cook Medical, Bloomington, IN) is constructed of tightly coiled metal alloy, which is also quite resistant to external compressive forces. First employed in 2006 for refractory ureteral obstruction caused by retroperitoneal fibrosis (Borin et al., 2006), longer-term data indicates primary ureteral patency rates of 72% with acceptable tolerability (Kadlec et al., 2013). More recently, hybrid ureteral stents with hydrophilic polymer coating reinforced by metallic coils have been developed (Silhouette stent: Applied Medical, Rancho Santa Margarita, CA; Passage/Snake stent: ProSurg, San Jose, CA). *In vitro* testing indicates high resistance to extrinsic compression, though *in vivo* reports as to their clinical effectiveness are limited (Dauw et al., 2015; Hendlin et al., 2012).

Design

Self-retaining, double pigtail ureteral stents are ubiquitous (Fig. 12.37). Single pigtail urinary diversion catheters are also available and typically employed in cases of lower urinary tract diversion in which the distal end can emanate from the body into an ostomy. Open-ended, spiral-tipped, or whistle-tipped ureteral catheters are typically reserved for temporary ureteral catheterization as an aid to ureteral identification in radial abdominal or pelvic surgery. In an effort to increase patient tolerability, stents have been designed with novel distal ends to minimize bladder irritation. One such example is the Polaris Loop ureteral stent (Boston Scientific, Marlborough, MA). However, a randomized controlled trial comparing this stent to a traditional double pigtail ureteral stent failed to show any symptomatic benefit using a validated questionnaire (Davenport et al., 2011; Park et al., 2015).

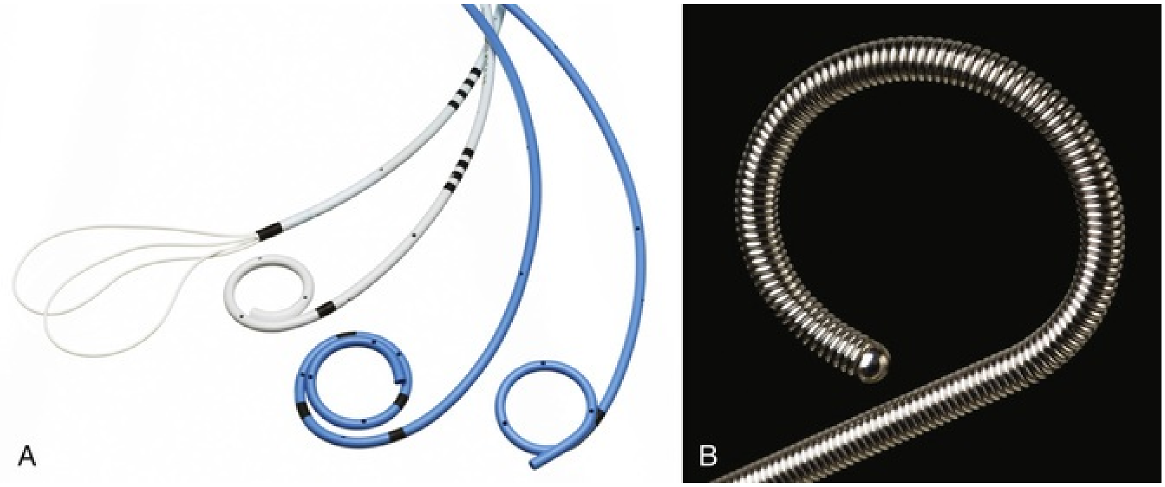

FIG. 12.37 Different stent designs. (A) Polaris Loop stent, Polaris Ultra stent, Percuflex Plus stent, and Contour VL stent. (B) Resonance metal stent. (A, Courtesy Boston Scientific, Marlborough, MA; B, Courtesy Cook Medical, Bloomington, IN.)

Stent Tolerance

Symptoms associated with ureteral stents are often quite bothersome to patients. The validated ureteral stent symptom questionnaire (USSQ), which can be used to measure the impact of ureteral stents on patient quality of life, is composed of 6 distinct domains addressed by 38 questions regarding urinary symptoms, pain, general health, work performance, sexual function, and additional problems (Joshi et al., 2003a). Using data from the initial cohort of patients completing the USSQ, urinary symptoms were present in 78% of patients, 80% felt that pain limited daily activities, 32% reported some degree of sexual dysfunction, and more than 50% reported decreased ability to work (Joshi et al., 2003b).

In an effort to reduce patient discomfort related to ureteral stents, investigators have evaluated a multitude of stent-specific factors such as stent length and diameter and a variety of pharmacologic agents. In a study evaluating patients with either a 22-, 24-, or 26-cm ureteral stent, bladder symptoms, notably urinary urgency and frequency, were more common as stent length increased, yet there was no difference in flank discomfort (Ho et al., 2008). One marker of stent length is the position of the distal (bladder) curl of the ureteral stent. Although an initial study suggested that extension of the distal curl of the ureteral stent across the midline of the urinary bladder was associated with significant urinary symptoms but no appreciable difference in flank pain (Al-Kandari et al., 2007), in a recent large randomized controlled trial evaluating stent length using the validated USSQ questionnaire, the authors found no difference in urinary symptoms or flank pain in longer versus shorter ureteral stents (Calvert et al., 2013). Studies evaluating stent diameter and its association with pain have shown no association of stent-related discomfort with stent diameter (Damiano et al., 2005; Erturk et al., 2003; Lamb et al., 2011; Yakoubi et al., 2011; Zhou et al., 2015).

One of the major symptoms associated with ureteral stents is bladder discomfort presumed to be caused by interaction of the distal curl of the ureteral stent with the bladder mucosa. Systematic reviews and meta-analyses indicate that both alpha blockers and antimuscarinic medications are associated with improvement of bladder symptoms such as urgency and frequency associated with ureteral stents, though the individual randomized controlled trials are quite small (Kwon et al., 2015; Lamb et al., 2011; Yakoubi et al., 2011; Zhou et al., 2015).

Key Points: Retrograde Renal Drainage

- In general, the indications for retrograde renal drainage mirror those for antegrade renal drainage.
- Stent architecture (material, tip configuration) has not been shown to increase stent tolerability.
- Stent length and position have been associated with decreased bladder discomfort such as urgency and frequency of urination.
- Alpha blockers and antimuscarinic medications have been associated with improved stent tolerability.

Principles of Urologic Endoscopy

Brian Duty MD, Michael Joseph Conlin MD, MCR

Introduction

The development of endoscopic tools and techniques has transformed many areas of medical and surgical care—perhaps none more than urology. Bladder outlet obstruction, urothelial tumors, ureteral obstruction, and nephrolithiasis are just a few of the urologic conditions revolutionized by endoscopic procedures.

This chapter will highlight significant events in the history of modern endoscope development, then describe contemporary video-endoscopic equipment. We will then explain in detail the indications, patient preparation, and techniques of cystourethroscopy and ureteropyeloscopy.

History of Endoscopy

Attempts to look inside the human body date back to antiquity. Little progress was made until 1806, when Philipp Bozzini developed the first “modern” endoscope (Engel, 2003). The Lichtleiter or “Light Conductor” used angled mirrors to conduct candlelight from a sharkskin-covered box into the body through aluminum tubing. In 1853, the French urologist Antonin Jean Desormeaux introduced a smaller profile endoscope with improved mirrors that utilized a kerosene lamp for illumination (Shah, 2002). He excised a urethral papilloma through this instrument, and he became the first individual to perform a therapeutic endoscopic procedure.

In 1877, Max Nitze moved the source of illumination (water-cooled electric platinum filament) to the end of the instrument and utilized a series of optical lenses placed at precise distances along the length of a hollow, air-filled scope to conduct and magnify the image (Herr, 2006). Few design improvements occurred—save development of the Amici prism in 1906, which allowed 90-degree offset images to maintain correct orientation—until 1966, when Harold Hopkins developed his rod-lens system (Gow, 1998). By abandoning hollow-chamber optical relay lenses for a series of glass rods with only short gaps of air between them, Hopkins was able to improve light transmission and decrease scope size. Hopkins’ rod-lens paved the way for contemporary rigid cystoscopes and the first rigid ureteroscope in 1979 (Lyon et al., 1979).

In 1854, John Tyndall demonstrated that light could travel through a curved stream of water by internal reflection (Whewell et al., 1854). This finding led to drawing molten glass into flexible, small-diameter fibers for light transmission. The development of fiber optics made possible the creation of flexible endoscopes. In 1964, Marshall reported the first application of flexible ureteroscopy (Marshall, 1964). However, the utility of flexible ureteroscopes was severely limited until the addition of a working channel and active tip deflection in the early 1980s (Bagley et al., 1983).

Although still widely used, fiber-optic endoscopes are fragile and have limited optical resolution. In 1970, Boyle and Smith developed the charge-coupled device (CCD), a sensor with the ability to convert photons into a digital image (Samplaski and Jones, 2009). Technical advances over the past three decades allowed placement of CCD sensors onto the distal tip of scopes. Introduced in 2005, the ACMI DCN-2010 flexible cystoscope was the first commercially available digital endoscope (Natalin and Landman, 2009). **Compared with rod-lens and fiber-optic bundle systems, digital sensor technology offers improved image resolution and durability without the need for a separate light cable and camera** (Quayle et al., 2005).

Basic Equipment and Video-Endoscopic Systems

At minimum, cystourethroscopy requires irrigation fluid, a light source, and an endoscope. Irrigation fluid should be normal saline routinely or a solution free from electrolytes such as glycine or mannitol when *monopolar* electrocautery is required. Using *bipolar* electrocautery permits the use of normal saline for transurethral surgical procedures, avoiding the potential complications of these other solutions. Sterile water should be avoided because of the small risk for absorption, electrolyte disturbance, and hemolysis.

A high-intensity xenon or halogen external light source delivers white light through a fiber-optic cable and endoscope to the field of view. Modern light source units feature light-level detection and automatic light-output adjustment to provide constant illumination.

First introduced into urologic practice in 2007, narrow-band imaging utilizes only blue (415 nm) and green (540 nm) wavelengths to image the urothelium (Bryan et al., 2008). These wavelengths are strongly absorbed by hemoglobin, enhancing the visibility of urothelial capillaries, small papillary lesions, and carcinoma in-situ. A meta-analysis of 8 studies including 1022 patients found that narrow-band imaging improves detection accuracy of noninvasive lesions, including carcinoma in situ (Zheng et al., 2012). These findings were supported by a more recent randomized multicenter study, which found narrow-band imaging to be superior to white-light cystoscopy for detecting non–muscle-invasive bladder cancer (Ye et al., 2015).

Although it is possible to view the image through the optical eyepiece of the endoscope, a camera is commonly used that allows the image to be displayed on a monitor that is part of a dedicated fixed or mobile video-endoscopic tower (Fig. 13.1). Video-endoscopic units have several advantages including better visualization, which enhances patient safety and surgical training; decreased risk for bodily fluid exposure; and improved surgeon ergonomics.

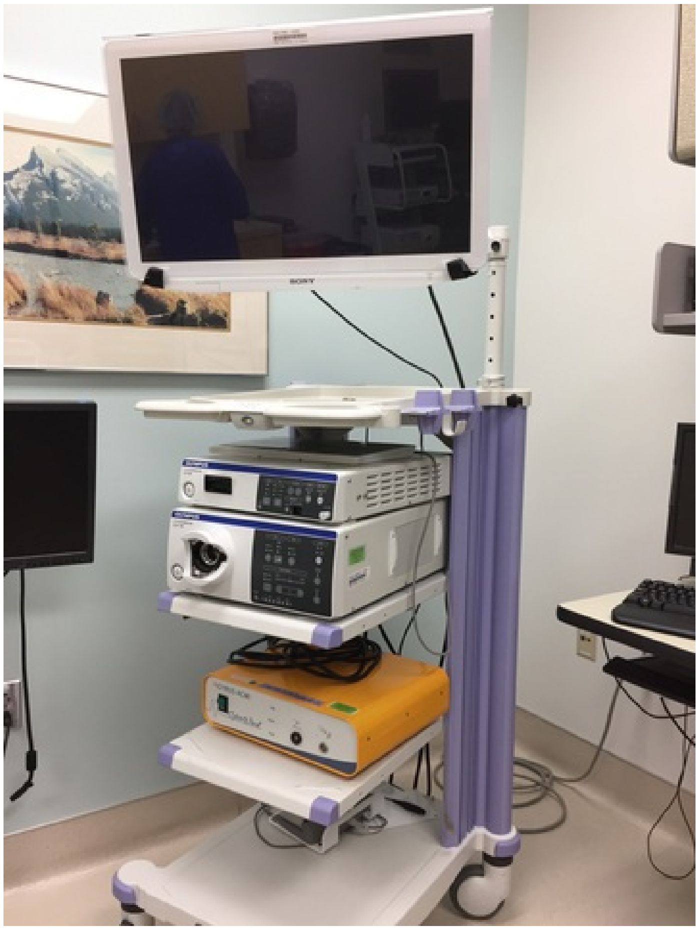

FIG. 13.1 Videoendoscopic unit consisting of a fixed tower, monitor, light source, image processor, video-recording device, and printer.

Traditional video-endoscopic systems consist of a light source, endoscope camera, image processor/recorder, and monitor. Newer digital endoscopes eliminate the need for an external camera and incorporate the light source and video cable into a single, built-in housing (Fig. 13.2). In the traditional system, a series of glass rods or fiber-optic bundles transmits the endoscopic image to the eyepiece. The external camera's CCD chip receives the optical image and produces an electrical charge (voltage waveform). The unit's video processor then converts the analog voltage waveform into a digital video signal that is sent to the monitor. In contrast, digital endoscope systems have the CCD chip located at the distal end of the endoscope. The image is immediately converted into an electrical signal that is managed by the video processor without the need for internal optics or an external CCD camera.

Cystourethroscopy

Indications

Cystourethroscopy is the most common office-based procedure in urology (Lee et al., 2002). Routinely performed in both the office and operating room, cystourethroscopy provides direct visualization of the urethra and bladder. Table 13.1 summarizes the indications for office-based cystourethroscopy. Most are for diagnostic purposes, but transurethral therapeutic procedures may also be performed. A frequent reason for cystourethroscopy is the evaluation of microscopic or gross hematuria. Besides direct inspection of the lower urinary tract, cystourethroscopy permits collection of cytologic specimens and retrograde pyelography in patients who are not candidates for intravenous contrast.

TABLE 13.1

Indications for Outpatient Cystourethroscopy

Hematuria	Gross
	Microscopic
Malignancy	Urethral cancer
	Bladder cancer
	Atypical cytology
	Upper tract transitional cell carcinoma surveillance
Lower Urinary Tract Symptoms	Recurrent urinary tract infections Obstructive voiding symptoms
	Irritative voiding symptoms
	Urinary incontinence
	Chronic pelvic pain syndrome
	Urethral stricture disease
Miscellaneous	Trauma
	Bladder abnormalities seen on imaging
	Removal of foreign bodies and small bladder stones
	Hematospermia
	Obstructive azoospermia

Urothelial carcinoma surveillance is another routine indication for cystourethroscopy. Small urothelial lesions may be biopsied and fulgurated in clinic. Upper tract surveillance may be accomplished by selective ureteral catheterization with retrograde pyelography, upper-tract washes for cytology, and brush biopsies for histologic evaluation.

Cystoscopy may be used in the assessment of lower urinary tract complaints such as recurrent infections, voiding dysfunction, and chronic pelvic pain. In select cases, urethral strictures, bladder stones, and foreign bodies may be treated in the office. Ureteral stents can also be placed or exchanged in clinic with fluoroscopic assistance.

Equipment

Cystourethroscopes are available in a variety of sizes and come in both rigid and flexible models. Sizes are expressed in French (Fr) gauge. **Devised by French instrument designer Joseph-Frédéric-Benoît Charrière (1803 to 1876), a 1-Fr device has a circumference of $\frac{1}{3}$ of a millimeter** (Osborn and Baron, 2006).

Rigid cystoscopes utilize the Hopkins rod-lens optical system, which provides improved optical clarity compared with the fiber-optic bundles used in flexible endoscopes (Lyon et al., 1979). Rigid cystourethroscopes have larger working channels than flexible scopes, resulting in increased irrigation flow and the ability to use a greater variety of working instruments. Rigid scopes are also easier to control with one hand, freeing the surgeon's second hand to manipulate ancillary tools.

In contrast, the smaller size of flexible cystourethroscopes improves patient comfort, making them ideal for office-based procedures. Endoscope passage does not require the patient to be in the frog-leg or lithotomy position. Their active tip deflection makes it easier to thoroughly inspect the bladder and negotiate an elevated bladder neck or median lobe of the prostate.

Rigid Cystourethroscopes

Rigid cystourethroscopes are manufactured in sets consisting of an optical lens, bridge, sheath, and obturator (Fig. 13.3). Configurations differ by vendor (Table 13.2). Optical lenses come with tip angles ranging from 0 to 120 degrees. Visualization of the urethra is best performed with a 0- or 12-degree lens. A 25- or 30-degree lens is commonly used for therapeutic purposes. A 70- or 120-degree lens may be required to thoroughly inspect the anterior and inferolateral walls, dome, and neck of the bladder.

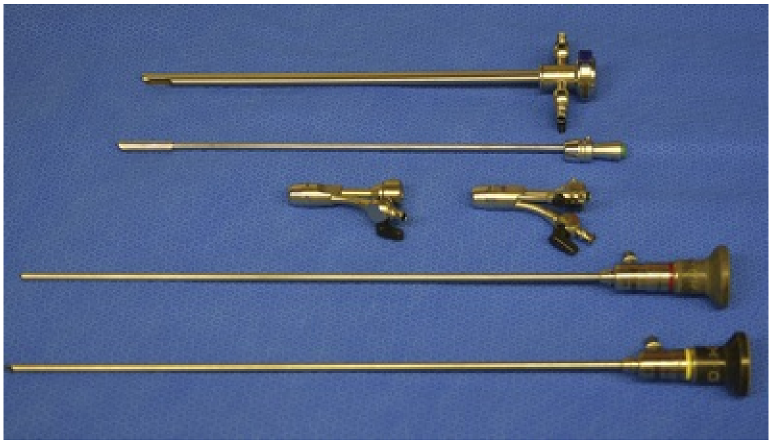

FIG. 13.3 Rigid cystourethroscope set consisting of sheath, obturator, bridges, and lenses *(from top to bottom)*.

Fr, French; *SB,* single bridge; *DB,* dual bridge.

The bridge connects the optical lens to the sheath. Diagnostic bridges do not have a working channel. Therapeutic bridges have one or two working channels. Patients with an elevated bladder neck, large median lobe of the prostate, or ureteroneocystostomy may require use of an Albarran's bridge. This specialized bridge contains a lever that deflects wires and catheters passed through the working channel to facilitate ureteral orifice canalization (Fig. 13.4).

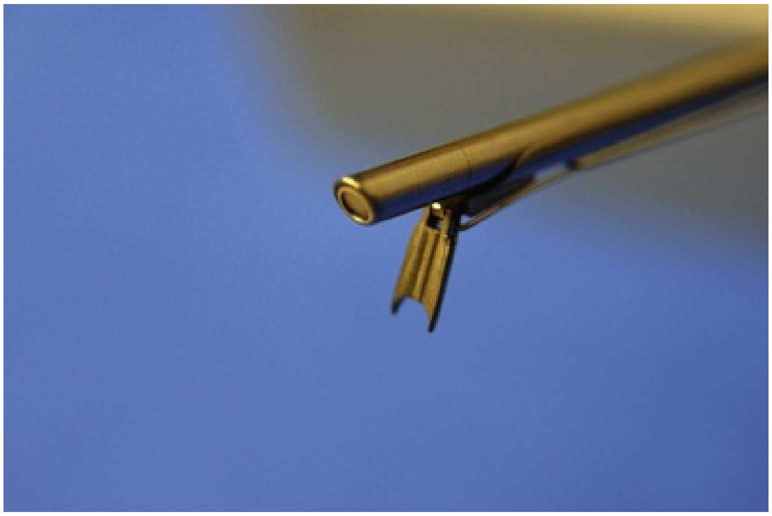

FIG. 13.4 Albarran's bridge, which is used to deflect wires and catheters passed through the rigid cystoscope working channel.

Cystourethroscope sheaths come in a variety of sizes. Most have markings indicating the size of the sheath and associated working channels (Fig. 13.5). Smaller sheaths (15 and 17 Fr) are ideal for diagnostic cystoscopy, with larger models being used for therapeutic procedures requiring improved irrigant flow and larger working channels. Each sheath has an associated obturator that blunts the distal end of the sheath for passage into the bladder without visual assistance. In most cases, "blind" endoscope passage should only be performed in women.

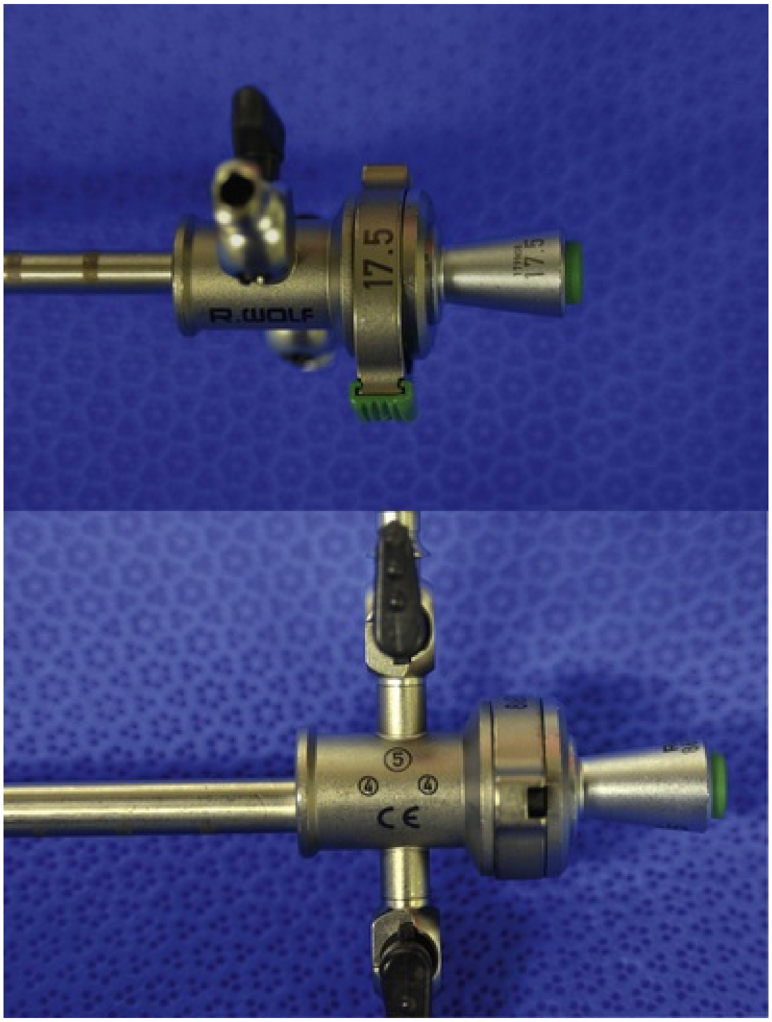

FIG. 13.5 Markings on rigid cystoscope sheath. The largest number on the base of the scope indicates the outer diameter (17.5 Fr). The numbers on the side of the sheath indicate the maximum working channel size when a dual bridge is used (4 Fr for both lumens) or when a single bridge is employed (5 Fr).

Flexible Cystourethroscopes

Flexible cystourethroscopes range between 16 and 17 Fr. Models differ with regard to tip deflection, direction of view, field of view, working channel size, illumination, and optics (Table 13.3). Most models have an "inline" eyepiece lens and produce a field of view of approximately 120 degrees. Tip deflection ranges between 120 and 210 degrees and is either intuitive (same direction as lever deflection) or counterintuitive (opposite direction of lever deflection). Irrigation and instrument passage occurs through the same working channel. Photodynamic and narrow-band imaging capabilities are increasingly common.

TABLE 13.3

Flexible Cytourethroscopes

MANUFACTURER	OPTICS	DEFLECTION	DIRECTION OF VIEW	FIELD OF VIEW	WORK LENG
Karl Storz	Fiber-optic • Multiple models	Up 210 degrees Down 140 degrees	0 degrees	110 degrees	37 cm
	Digital (standard-definition) • Multiple models	Up 210 degrees Down 140 degrees	0 degrees	120 degrees	37 cm
Olympus	Fiber-optic • Model CYF-5	Up 210 degrees Down 120 degrees	0 degrees	120 degrees	38 cm
	Digital (standard-definition) • Model CYF-V2	Up 210 degrees Down 120 degrees	0 degrees	120 degrees	38 cm
	Digital (high-definition) • Model CYF-VH	Up 210 degrees Down 120 degrees	0 degrees	120 degrees	38 cm
Wolf	Fiber-optic • Model 7305	Up 210 degrees Down 150 degrees	0 degrees	120 degrees	40 cm

Flexible cystourethroscopes are available in fiber-optic and digital models. Digital scopes do not require focusing or white balancing. They are now available in high-definition (1920 × 1080 pixels) and standard-definition (720 × 480 pixels) models. An *in vitro* study compared the resolution, contrast evaluation, depth of field, color representation, and illumination of fiber-optic, standard-definition, and high-definition flexible cystoscopes (Lusch et al., 2013). All three scopes were manufactured by Olympus (Olympus; Center Valley, PA). Compared with the fiber-optic and standard-definition models, the high-definition scope had a significantly higher resolution and depth of field. The high-definition scope's resolution was five times greater and had a 37% larger image than the standard-definition model. Color representation was only slightly better, and there was no difference in contrast evaluation among the three models. Illumination was significantly better in the fiber-optic model compared with both digital cystoscopes.

A randomized study of 1022 flexible cystoscopy cases compared optics, performance, and durability of fiber-optic and standard-definition digital scopes (Okhunov et al., 2009). There was a trend toward improved mean surgeon optical ranking in favor of the digital scopes ($p = 0.076$). There was no difference in durability between the models. Only two cystoscopes required repair (0.2% incidence rate), and both were damaged when the endoscope was placed in a storage case rather than during usage.

Data from an independent endoscope repair company found that flexible cystoscopes require less than one repair every 2 years (Canales et al., 2007). The most common repair was to the rubber overlying the distal flexible segment. Unlike flexible ureteroscopes, flexible cystourethroscopes are robust, likely making the optical mechanism a lesser determinant of scope durability.

Patient Preparation

Informed consent must be obtained before performing any cystoscopic procedure. A urinalysis and urine culture, if indicated, should be completed before cystoscopy. All urinary tract infections must be treated given the risk for bacteremia and sepsis after lower urinary tract manipulation.

Both the American Urological Association (AUA) and European Association of Urology (EAU) have published recommendations regarding periprocedural antibiotics. The AUA's Best Practice Policy Statement on Urologic Surgery Antimicrobial Prophylaxis was originally published in 2008 and was most recently amended in 2012 (Wolf et al., 2008). The EAU's Urological Infections guidelines were first published in 2001 and have been updated through 2017

(Bonkat et al., 2017).

Neither organization recommends antimicrobial prophylaxis for routine diagnostic cystoscopy in the absence of patient-related risk factors (Table 13.4). **The AUA recommends prophylaxis lasting less than 24 hours for therapeutic lower urinary tract procedures such as transurethral resection of the bladder and prostate.** This recommendation is largely based on a meta-analysis of 32 randomized controlled trials evaluating antimicrobial prophylaxis before transurethral resection of the prostate, which showed a decrease in bacteriuria, bacteremia, symptomatic urinary tract infection, and high-grade fever (Berry and Barratt, 2002). Given a lack of controlled trials pertaining to transurethral bladder procedures, the EAU guidelines leave prophylaxis at the provider's discretion.

TABLE 13.4

Patient Risk Factors Precluding Simple Cystoscopy Without Antimicrobial Prophylaxis

AUA BEST PRACTICE POLICY STATEMENT	EAU UROLOGICAL INFECTIONS GUIDELINES
Advanced age Anatomic anomalies of the urinary tract Poor nutritional status Smoking Chronic corticosteroid use Immunodeficiency Externalized catheters Colonized endogenous/exogenous material Distant coexistent infection	Older age Diabetes mellitus Impaired immune system Malnutrition Extreme weight History of urinary tract infectionVIndwelling catheters/bacterial burden Previous instrumentation Genetic factors
Prolonged hospitalization	

AUA, American Urological Association; *EAU,* European Association of Urology.

The AUA recommends either a fluoroquinolone or trimethoprim-sulfamethoxazole as the prophylactic agent of choice. Alternative agents include an aminoglycoside with or without ampicillin, a first- or second-generation cephalosporin, or amoxicillin/clavulanate. However, the Best Practice Policy has not been updated since 2012, and there are increasing concerns about the rising incidence of fluoroquinolone resistance (Marino Sabo and Stern, 2014). Consequently, the EAU guidelines state, “knowledge of the local pathogen profiles, susceptibility and virulence is mandatory.”

Before cystourethroscopy, the skin is prepared with an antiseptic agent. Most commercially available agents contain iodophors or chlorhexidine gluconate in either an aqueous or alcohol-based solution. **Both chlorhexidine gluconate and alcohol-based solutions can damage mucous membranes and therefore are not recommended on the genitalia. Aqueous-based iodophor-containing products such as Betadine are safe on all skin surfaces regardless of patient age.**

After application of an antiseptic agent, lubricating gel is instilled into the urethra of patients undergoing flexible cystourethroscopy. Either a plain or lidocaine gel may be used. **A meta-analysis of four randomized trials involving 411 patients found that patients receiving lidocaine gel were 1.7 times less likely to experience moderate to severe pain during the procedure** (Aaronson et al., 2009). **However, only one of the four trials showed a statistical benefit to lidocaine gel, which is consistent with a larger meta-analysis involving 817 patients from 9 randomized trials that showed no difference in procedure tolerance** (Patel et al., 2008a).

Other techniques have been employed to improve patient comfort during flexible cystourethroscopy. For most men, the least comfortable portion of the procedure is during scope passage through the membranous urethra (Taghizadeh et al., 2006). In an attempt to improve tolerance, a randomized trial was performed to evaluate the effectiveness of increased hydrostatic pressure of the irrigation solution (Gunendran et al., 2008). Manual compression of the irrigation bag during passage of the scope through the membranous urethra was compared with gravity irrigation alone in 151 men undergoing flexible cystourethroscopy. A significant improvement on an analog pain scale was noted (1.38 vs. 3.00, $p < 0.001$) in the manual compression group.

The impact of being allowed to observe the procedure has also been evaluated. One hundred male patients undergoing flexible cystourethroscopy were randomized; one-half of the subjects were allowed to watch the procedure on a video monitor, and the remaining patients were not (Patel et al., 2007). **Men who viewed the procedure had significantly less pain on a 100-mm visual analog pain scale (14 vs. 23, $p = 0.02$). These findings were confirmed by another randomized study of 76 male patients** (Soomro et al., 2011). **Men in the observation group had less pain and lower postprocedure pulse rates.** In contrast, a randomized study on 100 women undergoing office-based cystoscopy with a 17-Fr rigid scope found no difference in procedural pain (Patel et al., 2008b).

The potentially calming effect of music has also been examined. Seventy men undergoing flexible cystoscopy were randomized to either no music or classical music played during the procedure (Yeo et al., 2013). Patients listening to classical music had significantly less pain, higher satisfaction, lower postprocedure pulse rates, and lower systolic blood pressures.

Technique

Before inserting the cystourethroscope, the external genitalia is inspected for cutaneous lesions and anatomic abnormalities. Mild meatal stenosis may be addressed with sequential metal dilators. Dilation should be performed to at least 2 Fr wider than the intended endoscope size.

In women, rigid cystourethroscope insertion is safest using the sheath obturator. The scope will often need to be directed anteriorly as it is advanced into the bladder. Flexible cystourethroscopes can often be inserted into the bladder like a Foley catheter with active deflection being used as needed.

In men, the penis is placed on maximal stretch to straighten the urethra. When passing a rigid cystourethroscope, the penis is typically grasped with all five digits of the surgeon's nondominant hand. With flexible cystourethroscopy, the penis is pinched between the third and fourth digits of the nondominant hand at the corona while the thumb and index finger help advance and direct the scope into the urethra (Fig. 13.6). In morbidly obese patients, it is often easier to lay the scope down, retract the pannus with the nondominant hand, and direct the tip of the flexible scope into the urethra like a Foley catheter. Once in the mid-penile urethra, the scope is placed in the dominant hand and advanced as usual.

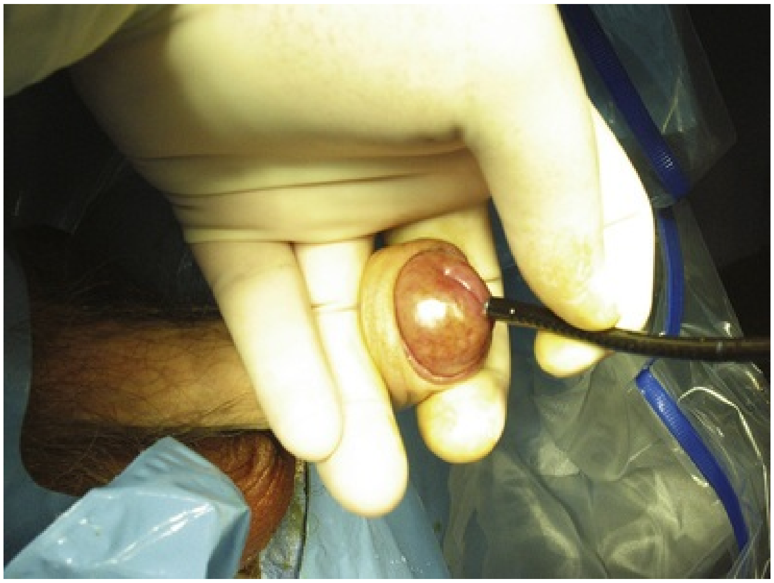

FIG. 13.6 During flexible cystoscopy, the distal penis is grasped between the surgeon's third and fourth fingers and placed on stretch while the thumb and index finger advance the cystoscope into the urethral meatus.

The penis should be angled 45 to 90 degrees relative to the abdominal wall while passing the scope through the anterior urethra. Once beyond the membranous urethra, the cystoscope is directed anteriorly to enter the bladder. With flexible cystoscopes, this is accomplished by active upward deflection, and with rigid cystoscopes by dropping the distal end of the scope toward the operative table.

The lower urinary tract is systematically evaluated under maximal irrigation as the scope is advanced. The penile and bulbar urethra are inspected for strictures. The periurethral glands of Littre should be noted as they drain into the urethra dorsally. Patients, in particular young men, should be encouraged to relax as much as possible as the scope is advanced through the membranous urethra. Once in the prostatic urethra, the verumontanum and utricle are identified posteriorly. The length of the posterior urethra is measured, and the size of the prostatic lobes are evaluated.

Once in the bladder, the mucosa is carefully inspected. Rigid cystoscopy is usually begun with a 25- or 30-degree lens. The floor of the bladder and trigone are surveyed. The number, location, and configuration of the ureteral orifices are noted. Efflux from each ureter should be observed for the presence of gross blood. The remainder of the bladder is inspected for stones, trabeculation, cellules, diverticula, erythematous patches, and papillary and sessile lesions. Visualization of the lateral walls is accomplished by rotating the cystoscope while keeping the camera orientation fixed. The dome, anterior and posterolateral walls are inspected with a 70- or 120-degree lens. After completing the procedure, the bladder is emptied, and the endoscope is withdrawn. If a Foley catheter is to be placed after the cystoscopy, it is best to leave the bladder at least partially full before removing the cystoscope.

Special Circumstances

Suprapubic Cystostomy

The indications for cystoscopy in patients with suprapubic cystostomy tubes are the same as those without chronic indwelling catheters. However, these individuals are at increased risk for infection, bladder calculi, and bladder cancer (El Masri et al., 2014; Subramonian et al., 2004; Welk et al., 2013). There is no level-one data showing that use of surveillance cystoscopy improves survival in patients with long-term indwelling catheters. As a result, controversy exists regarding the utility of surveillance cystoscopy in patients with neurogenic bladder and long-term indwelling catheters (Vince and Klausner, 2017).

Cystoscopy may be performed through the urethra or the patient's suprapubic tract. However, many patients with long-term suprapubic tubes suffer from urethral stricture disease, making the suprapubic tract the only feasible route to the bladder. Every effort should be made to avoid endoscopy through a suprapubic tract until it has had time to mature, which usually takes several weeks from the time of creation. There will be occasions when endoscopy through an immature suprapubic tract is required. When needed, it is helpful to place a wire through the suprapubic tube before removal. This safety wire helps maintain access to the bladder and can serve to guide placement of the endoscope. This technique is also helpful in morbidly obese patients with long, often tortuous tracts.

Ureteral access is often challenging during rigid cystoscopy through the cystostomy tract because of the acute angle required to cannulate the ureteral orifice. Angled catheters such as the Kumpe catheter (Cook Medical; Bloomington, IN) or use of an Albarran's deflector may facilitate ureteral access. Using a flexible cystoscope will often overcome these problems. Alternatively, patients with low-grade urethral strictures may be able to accommodate transurethral passage of a semirigid ureteroscope facilitating standard ureteral access. Lastly, the ureteral orifices may be difficult to identify because of edema caused by the chronic suprapubic tube. Administering intravenous indigo carmine or methylene blue early in the procedure may help visualize the ureteral orifices.

Continent Urinary Diversions

There are two general classes of continent urinary diversions after cystectomy. Orthotopic urinary diversions are anastomosed to the urethra and rely on the striated urinary sphincter to maintain continence. Continent cutaneous reservoirs utilize a catheterizable channel spanning from the diversion to the anterior abdominal wall. The catheterizable channel may be composed of the appendix (Mitrofanoff), tapered/imbricated terminal ileum and ileocecal valve, or an intussuscepted nipple valve.

Before undertaking any endoscopic procedure involving a continent urinary diversion, it is imperative to obtain the operative note. It's important to know the bowel segment used, type and location of the ureteroenteric anastomoses, continence mechanism employed, and if an afferent limb was created.

Transurethral access to orthotopic diversions is often straightforward and can be accomplished using a rigid cystoscope. If a urethral anastomotic contracture is noted and the patient is not suffering from outlet obstruction, then it is advisable to use the smallest scope possible rather than dilate or incise the stricture to prevent worsening urinary incontinence.

Diagnostic endoscopy of continent cutaneous reservoirs is best accomplished using a flexible cystoscope through the catheterizable channel. All but the most straightforward therapeutic procedures should be performed percutaneously given the continence mechanisms are often fragile and excess manipulation may result in either stomal stenosis or urinary incontinence (L'Esperance et al., 2004). Preoperative computed tomography or intraoperative ultrasound should be used to minimize the risk for bowel injury during percutaneous access.

Once within the diversion, visualization is often challenging because of mucus, mucosal folds, bowel peristalsis, and, if present, tortuous afferent limb. Begin by irrigating out all of the mucus. Irrigation should then be used judiciously. Too little irrigation will make mucosal folds more prominent and impair visualization, but overdistention will prevent access to the afferent limb and will often result in troublesome retroflexion of flexible cystoscopes. Once again, ancillary techniques such as using angled catheters and indigo carmine or methylene blue may be required.

Key Points: Cystourethroscopy

- Rigid cystourethroscopes are manufactured in sets consisting of an optical lens, bridge, sheath, and obturator.
- Flexible cystourethroscopes are available in fiber-optic, standard-definition, and high-definition digital models.
- Cystourethroscope sizes are expressed using the French gauge system with 1 Fr equaling one-third of a millimeter in circumference.
- The smallest-diameter cystourethroscope that can be used to perform the procedure should be selected to decrease the risk for genitourinary tract trauma.
- Antimicrobial prophylaxis is not recommended for diagnostic cystourethroscopy unless patient-related risk factors are present.
- Increasing the hydrostatic pressure during scope passage and allowing men to observe the procedure have been prospectively shown to improve patient comfort during flexible cystourethroscopy.

Upper-Tract Endoscopy

Indications

Urolithiasis

Surgical treatment of nephrolithiasis is the most common indication for upper-tract endoscopy. The AUA/Endourological Society guidelines on surgical management of stones recommend either shock wave lithotripsy (SWL) or ureteroscopy for ureteral calculi (Assimos et al., 2016). Clinicians are encouraged to discuss with their patients the higher stone-free rate but greater morbidity associated with ureteroscopy compared with SWL. The EAU guidelines on urolithiasis also indicate that ureteroscopy and SWL are appropriate modalities for smaller ureteral stones, but ureteroscopy is preferred for calculi larger than 10 mm because of its higher stone-free rate (Türk et al., 2017).

Per the AUA/Endourological Society guidelines, non–lower-pole intrarenal stones measuring less than 20 mm may be treated with either SWL or ureteroscopy. Stones larger than 20 mm should be managed with percutaneous nephrolithotomy (PCNL). **However, patients with comorbidities making percutaneous treatment prohibitively dangerous have been successfully managed with ureteroscopy. Two studies have reported stone-free rates of 91% and 93% for ureteroscopic treatment of patients with stones larger than 2 cm** (Grasso et al., 1997; Breda et al., 2008). Lower-pole stones less than 10 mm can be managed with either SWL or ureteroscopy. Consideration for PCNL should be given to stones larger than 10 mm in the lower pole given its superior stone-free rate. The EAU guidelines are very similar in their recommendations regarding intrarenal stone management. However, they do indicate that SWL for lower-pole stones between 10 and 20 mm may be considered as long as there are no unfavorable factors, such as the presence of shock wave–resistant stones (calcium oxalate monohydrate, brushite, or cystine), a steep infundibular-pelvic angle, a long lower-pole calyx (>10 mm), a narrow infundibulum (<5 mm), or a skin-to-stone distance exceeding 10 cm.

Upper Urinary Tract Urothelial Carcinoma

The EAU guidelines on upper urinary tract urothelial carcinoma recommend performing diagnostic ureteroscopy when imaging is equivocal or conservative management is being considered (Keeley et al., 1997). Despite yielding only a small amount of material for evaluation, ureteroscopic biopsy has been shown to accurately predict final pathologic grade in approximately 90% of patients (Rojas et al., 2013). Diagnostic ureteroscopy has not been shown to negatively impact long-term or disease-specific survival in patients undergoing extirpative therapy (Ishikawa et al., 2010). However, a recent study reported an increased risk for intravesical recurrence, highlighting the need for long-term bladder surveillance (Yoo et al., 2017).

In the past, urologists reserved endoscopic treatment of upper tract urothelial tumors for compelling indications such as solitary kidney, renal insufficiency, bilateral upper tract urothelial cell carcinoma, or significant medical comorbidities. However, with improvements in instrumentation and technique, endoscopic treatment of low-grade disease has been reported to be a reasonable option without compromising survival (Cutress et al., 2012; Grasso et al., 2012). Larger tumors can be challenging to fully ablate in one session, prompting reports of percutaneous nephroscopy with electroresection (Cutress et al., 2012; Irwin et al., 2010; Motamedinia et al., 2016; Strijbos and van der Heij, 2016). Nevertheless, when feasible, ureteroscopy is preferable because it avoids the small, but reported risk for seeding the percutaneous tract and retroperitoneum with tumor (Sengupta and Harewood, 1998; Sharma et al., 1994).

Ureteropelvic Junction Obstruction and Ureteral Stricture

Despite the widespread adoption of laparoscopic and robotic-assisted pyeloplasty, endopyelotomy remains a common treatment for patients with ureteropelvic junction (UPJ) obstruction (Jacobs et al., 2018). Endopyelotomy can be performed percutaneously or ureteroscopically. The ureteroscopic approach has the advantage of avoiding the potential morbidity of percutaneous renal access, allowing the procedure to be performed in an outpatient setting.

There are two situations in which ureteroscopic endopyelotomy may not be the preferred approach. Patients with concomitant renal calculi should be treated percutaneously to allow simultaneous stone removal and endopyelotomy. Also, several studies have demonstrated a decreased success rate with endopyelotomy in patients who have vessels crossing at the UPJ (Bagley et al., 1995; Conlin and Bagley, 1998; Tawfiek et al., 1999; Van Cangh et al., 1994). **It may be best to limit ureteroscopic endopyelotomy to those patients with a documented absence of crossing vessels and to treat those with crossing vessels using**

laparoscopic ureteropyeloplasty.

Patients with ureteral strictures can also be managed from a ureteroscopic approach. The technique is nearly identical to the ureteroscopic endopyelotomy technique. Endoureterotomy is less successful in patients with ureteral strictures longer than 1.5 cm, allograft ureters, previously irradiated ureters, ureters draining poorly functioning kidneys, and ureteral-enteral anastomotic strictures (Wolf et al., 1997). Ureteroscopic incision of short ureteral strictures in otherwise healthy ureters is a reasonably successful treatment option (Emiliani and Breda, 2015).

Other Indications for Ureteroscopy

Diagnostic ureteroscopy can be performed for persistent, unexplained positive cytology, filling defects noted on excretory urography, and recurrent urinary tract infections localized to a single renal unit. With the miniaturization of flexible ureteroscopes, the safety of flexible ureteroscopy has increased significantly. Rather than relying on ureteropyelography alone, we can now safely and easily perform diagnostic ureteroscopy. Ureteroscopy has also been used for removal of foreign bodies including suture, proximally migrated ureteral stents, balloon catheters, and other fractured working instruments.

Benign essential hematuria can be diagnosed and treated with flexible ureteroscopy. This condition is defined as unilateral gross hematuria for which there is no radiographically defined cause (Bagley et al., 1987; Lano et al., 1979). These patients frequently have had studies including excretory urography, renal sonography, arteriography, or a combination of these. Flexible ureteroscopic inspection of the involved kidney usually results in diagnosis and successful treatment. The most common finding in patients with benign essential hematuria is a small hemangioma, which can often be fulgurated. Other endoscopic findings in patients with benign essential hematuria include small venous ruptures, papillary tumors, varices, and calculi (Dooley and Pietrow, 2004).

Equipment

Semirigid Ureteroscopes

Successful ureteroscopy (▶Video 13.1) requires a variety of instrumentation, most importantly suitable, modern ureteroscopes. Although larger rod lens rigid ureteroscopes are still available in some operating rooms, the smaller-diameter fiber-optic ureteroscopes are less traumatic, require ureteral dilation less often, and are equally capable.

Semirigid ureteroscopes are smaller in diameter because of the incorporation of fiber optics into their construction. Fiber-optic bundles consist of multiple glass fibers. Each fiber is coated with a cladding; an additional layer of glass with a different refractive index. This cladding improves the internal reflection, light transmission, and durability of the fiber-optic bundle. When the fibers are grouped randomly, such as those within a light bundle, they transmit light for illumination but no image. When the fibers are arranged coherently, the light from each fiber within the bundle will coalesce to transmit images.

Small lenses are attached to both ends of the image bundle to create a telescope. The number of fibers in the bundle and the type and orientation of the lenses determine the degree of image magnification, the field of view, and focusing ability for different fiber-optic endoscopes. For example, by changing the axis of the lens at the distal tip of the image bundle, the angle of view of the ureteroscope can be changed to improve the visibility of working instruments passed out of the working channel (Higashihara et al., 1990).

Improvements in image bundle construction allow closer packing of more fibers, resulting in improved image transmission, smaller outer diameters, and larger working channels in both rigid and flexible ureteroscopes. Manufacturers have also replaced the single-light bundle with two smaller bundles permitting a more centrally placed working channel and better distribution of the light within the field of view (Conlin et al., 1997).

Most current semirigid ureteroscopes have tip diameters of 7 Fr or less and working channels larger than 3 Fr. Semirigid ureteroscopes have either a large single or two smaller individual working channels. **An advantage of the separate working channels is improved irrigation through one open channel while a working instrument occupies the other. Independent working channels also permit passage of a lithotripsy device through one channel to fracture a trapped stone stuck in a basket in the other channel**. With a single channel, this may be impossible because of entanglement between the two working instruments. For these reasons, semirigid ureteroscopes with two separate working channels are preferred.

Eyepieces are commonly “in line” with the ureteroscope for a more natural insertion and use of the scope (Fig. 13.7). The offset eyepiece design makes possible a straight working channel, needed for less flexible working instruments like rigid biopsy forceps or pneumatic lithotripsy probes (Fig. 13.8). Increased availability and use of the holmium laser for ureteroscopic lithotripsy has decreased the need for ureteroscopes with offset eyepieces.

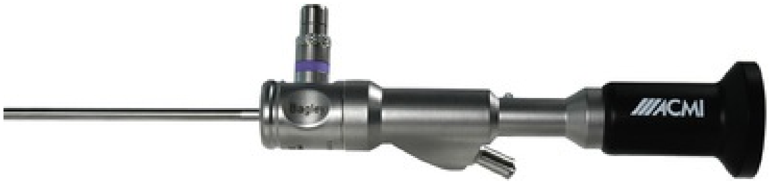

FIG. 13.7 Semirigid ureteroscope with an "in-line" eyepiece.

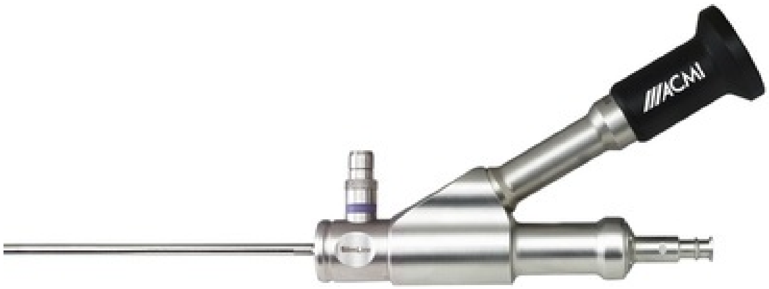

FIG. 13.8 Semirigid ureteroscope with an offset eyepiece, which has a straight working channel permitting passage of rigid instruments.

In the past, some urologists preferred larger ureteral resectoscopes (11.5 Fr) for large distal ureteral tumor resection and ureteroscopic endopyelotomies (Thomas et al., 1996). Preoperative ureteral stenting was necessary to allow passage of the larger-diameter ureteral resectoscope, especially to the UPJ. By using laser energy for tissue ablation and incision, urologists can avoid the more significant trauma of these ureteral resectoscopes.

Currently available semirigid ureteroscopes and their characteristics are listed in Table 13.5.

Flexible Ureteroscopes

The fundamental components of flexible ureteroscopes include the optical system, deflection mechanism, and working channel. The nondigital optical system consists of flexible fiber-optic image and light bundles. Improvements in the fiber-optic image bundles are similar to those in semirigid ureteroscopes, as discussed in the preceding section.

Active deflection of the flexible ureteroscope permits complete maneuverability within the intrarenal collecting system (Bagley, 1989). The deflecting mechanism control wires run the length of the ureteroscope from a manually operated lever mechanism, through moveable metal rings, to the distal end of the scope where they are fixed. Moving the lever up or down will pull the control wire through these rings and deflect the tip. When the tip moves in the same direction as the lever, the deflection is said to be “intuitive” (i.e., down is down, and up is up). Modern flexible ureteroscopes allow both up and down deflection in a single plane (Grasso and Bagley, 1994). **The plane of deflection is designated by the reticle seen as a notch within the field of view of the ureteroscope (Fig. 13.9). When maneuvering the flexible ureteroscope, it must be rotated to align the plane of deflection with the intended target.** The active deflection mechanism eventually “wears out” with repeated use, requiring repair or replacement of the ureteroscope. Improvements in the construction of the deflecting mechanism with each new generation of flexible ureteroscope continue to improve durability.

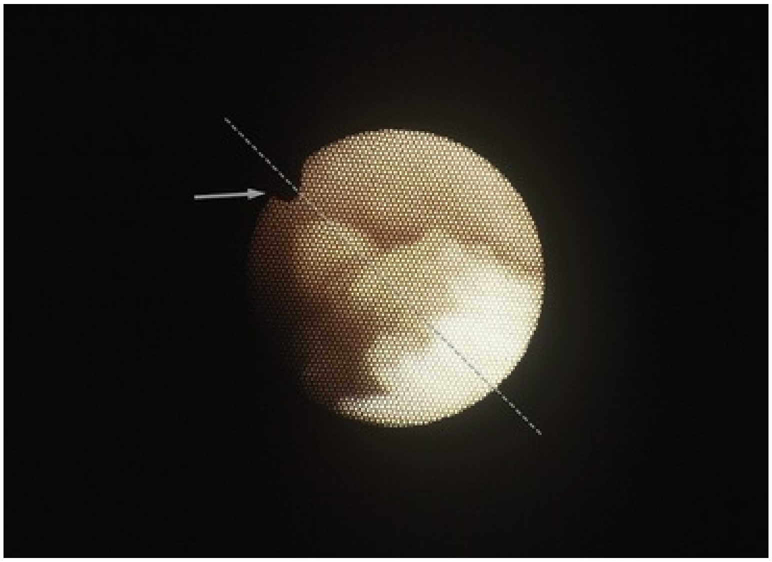

FIG. 13.9 Flexible ureteroscopic image showing the reticle *(arrow),* which designates the plane of deflection *(dotted line).*

Current flexible ureteroscopes permit more than 180 degrees of deflection. The amount of deflection necessary to reach the lower pole of the kidney varies among different patients. One group of investigators measured ureteroinfindibular angle (between the major axis of the ureter and the lower pole infundibulum) in 30 patients. They determined an average angle of 140 degrees with a maximum of 175 degrees (Bagley and Rittenberg, 1987). Active deflection of the ureteroscope of 180 degrees should allow visualization of the lower pole in most patients. However, reaching into the lower-pole calyx with the tip of the ureteroscope in a fashion that allows endoscopic work to be done can still be challenging.

Active deflection occurs only at the distal tip of the ureteroscope, and the deflected segment may not be long enough to reach the lower-pole calyx. Previous flexible ureteroscopes incorporated a flexible section of the ureteroscope just proximal to the point of active deflection. This secondary, passive deflection mechanism addressed the difficulty of reaching the lower pole in some patients. By passively bending the tip of the ureteroscope off of the superior margin of the renal pelvis, the point of deflection was moved proximally on the ureteroscope, effectively extending the tip of the ureteroscope. When passive deflection is used, the lower-pole calyx can be reached in most patients. Many of the failures to reach the lower pole will be in patients with significant hydronephrosis, which can limit the ability to engage passive secondary deflection.

Two recent innovations in ureteroscope deflection have improved ureteroscopic access to the lower pole. These are active secondary deflection and “exaggerated” deflection. The first ureteroscope incorporating active secondary deflection, the DUR-8 Elite, was developed by Circon-ACMI, now part of Olympus (Center Valley, PA). In addition to the primary deflection mechanism, there is a second control lever for active secondary deflection of 165 degrees at a more proximal location on the shaft, which extended the length of the deflected segment into the lower pole. This ureteroscope can assist the urologist to reach the lower pole even under conditions in which access with passive secondary deflection is not possible (Fig. 13.10). Locking the secondary deflection in place simplifies the use of primary deflection for manipulation of the tip within the lower-pole calyces. The usefulness of active secondary deflection was evaluated by Ankem et al. (2004), who found it helpful in cases in which the single deflection flexible instruments fail to access and treat upper urinary tract pathology. Despite these advantages, and because of more significant improvements in ureteroscope primary deflection, there is currently no available flexible ureteroscope with active secondary deflection.

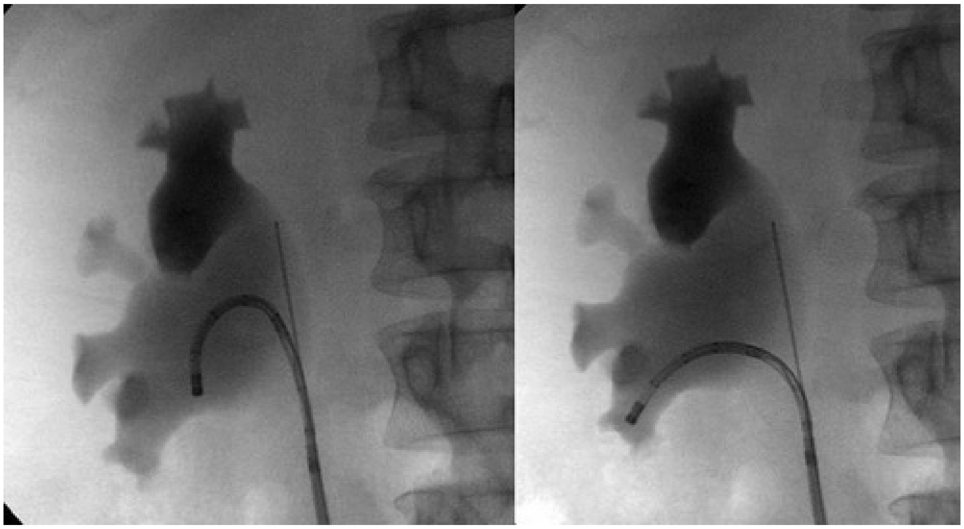

FIG. 13.10 Inability to access the lower-pole calyx with typical primary deflection *(left).* Successful access of the lower pole using active secondary deflection *(right).*

Karl Storz Endoscopy (Tuttlingen, Germany) introduced “exaggerated deflection” with their Flex-X model flexible ureteroscope (Johnson and Grasso, 2004). This modification of the deflection mechanism permits active primary deflection to greater than 300 degrees (Fig. 13.11). When approaching the lower-pole calyx, the deflected segment of the ureteroscope will effectively lengthen as it is deflected against the lower-pole infundibulum. This improvement of the deflection mechanism results in easier lower-pole access and improved deflection when using working instruments. Most modern ureteroscopes now incorporate similar enhancements in primary deflection that have significantly improved the ease of reaching the lower-pole calyces.

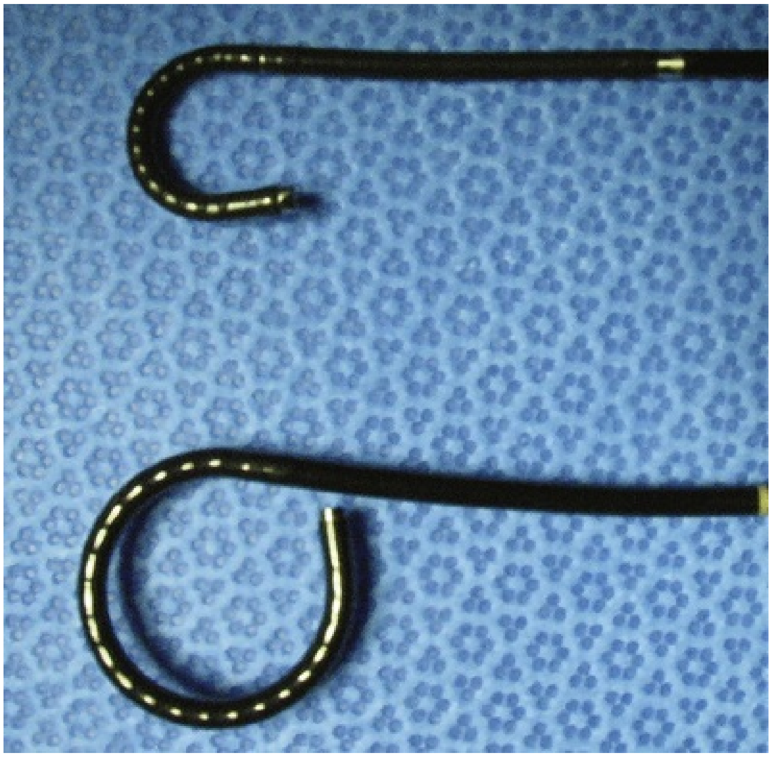

FIG. 13.11 Flexible ureteroscopes with standard primary deflection *(top)* and exaggerated primary deflection *(bottom).*

All currently available flexible ureteroscopes have working channels of 3.6 Fr diameter. Adequate irrigation is possible, even when using working devices up to 3 Fr. Higher-pressure irrigation will be necessary, especially when devices are present within the working channel (Bach et al., 2011). This higher-pressure irrigation can be delivered using a pressurized irrigation bag, roller pump, or handheld devices. The development of a dual-channel flexible ureteroscope, the Cobra from Richard Wolf (Vernon Hills, IL), is an innovation that can improve irrigation through the ureteroscope. The dual 3.3-Fr channels will permit unimpeded irrigation through one channel while the working instrument occupies the other (Haberman et al., 2011). One may also use both channels for working instruments, such as a laser and a basket, if necessary.

Digital Ureteroscopes

Digital flexible ureteroscopes have become the preferred upper tract endoscope for most urology services. Like digital flexible cystoscopes described earlier in this chapter, these ureteroscopes integrate the digital camera and light source within the endoscope. A separate camera head is unnecessary because the digital camera chip (CCD or CMOS) is incorporated into the tip of the endoscope. Because these devices do not require a fiber-optic image bundle, separate light cord, or camera head, they may be less prone to damage and have a longer lifespan.

Digital flexible ureteroscopes are larger in diameter than the smallest fiber-optic flexible ureteroscopes. One group of investigators prospectively compared digital and fiber-optic ureteroscopes to determine the influence of these larger-diameter digital scopes on patient outcomes. They found more frequent use of ureteral access sheaths and related complications in those patients undergoing ureteroscopy with a digital ureteroscope (Bach et al., 2012). In another analysis of the efficacy of digital and flexible ureteroscopes, investigators determined a statistically equivalent stone-free rate but a significantly shorter operative time in the digital group (Somani et al., 2013). The quicker procedures were likely caused by the improved visibility of the digital ureteroscopes (Fig. 13.12). Future digital ureteroscopes may advance miniaturization, optimize digital resolution, and improve durability.

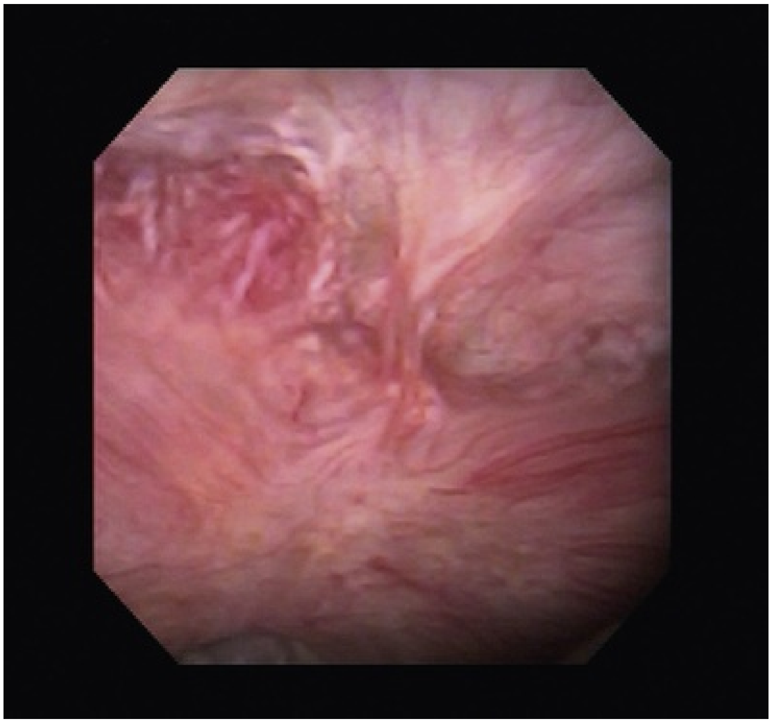

FIG. 13.12 Excellent optical clarity of a digital ureteroscope image of a compound calyx.

In 2015, Boston Scientific (Marlborough, MA) introduced the LithoVue, the first single-use flexible ureteroscope. The rationale for a single-use ureteroscope is to avoid the high cost associated with maintaining and repairing reusable endoscopes. Although the durability of flexible ureteroscopes varies in the literature, some studies have reported repair needed after an average of only three to five cases (Knudsen et al., 2010; Monga et al., 2006). Furthermore, refurbished scopes appear to be more prone to damage than new scopes (Carey et al., 2014). One study estimated that repair costs add $355 to each case (Kramolowsky et al., 2016).

The LithoVue ureteroscope has an LED light source at the tip and a digital CMOS sensor that provides a depth of field between 2 mm and 50 mm. The tip diameter is 7.7 Fr, and the shaft has a maximal outer diameter of 9.5 Fr. The scope contains a single working channel of 3.6 Fr and has 270-degree active deflection in both directions.

A cadaveric study comparing the LithoVue to nondisposable fiber-optic and digital ureteroscopes found the LithoVue to be comparable in visibility and scope maneuverability (Proietti et al., 2016). A prospective case-control study comparing the LithoVue to a reusable fiber-optic scope found that the LithoVue was associated with shorter procedure duration and comparable failure rates

(4.4% LithoVue vs. 7.7% reusable scope; *p* = 0.27) (Usawachintachit et al., 2017).

The economic impact of the LithoVue has not been definitively determined. Some studies report comparable costs associated with the LithoVue (Taguchi et al., 2017), and others report an economic benefit in select situations such as low-volume centers (Martin et al., 2017) or larger stones in the lower pole (Ozimek et al., 2017).

Given the potential advantages of disposable ureteroscopes, several companies are in the process of bringing competing products to the market. These include the Pusen (Zhuhai Pusen Medical Technology Company Limited, China), the YC-FR-A (YouCare Tech, China), and the NeoFlex (Neoscope, Inc.).

The specifications of currently available flexible ureteroscopes are detailed in Table 13.6.

Care and Sterilization

Rigid and flexible ureteroscopes are delicate instruments that need to be handled accordingly. Damage to the working channel, deflecting mechanism, or fibers within the image bundle can render the ureteroscope useless. One series reported that repairs of flexible ureteroscopes were necessary after only 3 to 13 hours of use (Afane et al., 2000). The repairs were usually caused by deterioration of the deflecting mechanism.

The working channels of flexible ureteroscopes are also easily damaged. This primarily occurs during passage of a small (200-micron) holmium laser fiber. **When inserting a fiber into a flexible ureteroscope that is even minimally deflected, the tip of the fiber may scrape the inner working channel. This can raise a small irregular area of the channel that will be more prone to damage.** With each subsequent pass of laser fibers or other working instruments, the channel is increasingly damaged and eventually perforated. Once perforated, sterilization of the flexible ureteroscope will result in fluid damage to the imaging system of the scope, making the scope unusable. **Firing the fiber within the working channel will also result in scope injury. The holmium laser may damage the working channel when the tip is very near the end of the working channel** (Fig. 13.13). Keeping the tip of the fiber within the central portion of the field of view when firing the laser should prevent collateral damage to the ureteroscope. **The "golden rule" of safe holmium laser lithotripsy is, "do not step on the pedal if you cannot see the tip of the fiber in contact with the stone." This will prevent injury to the ureter and damage to the ureteroscope**.

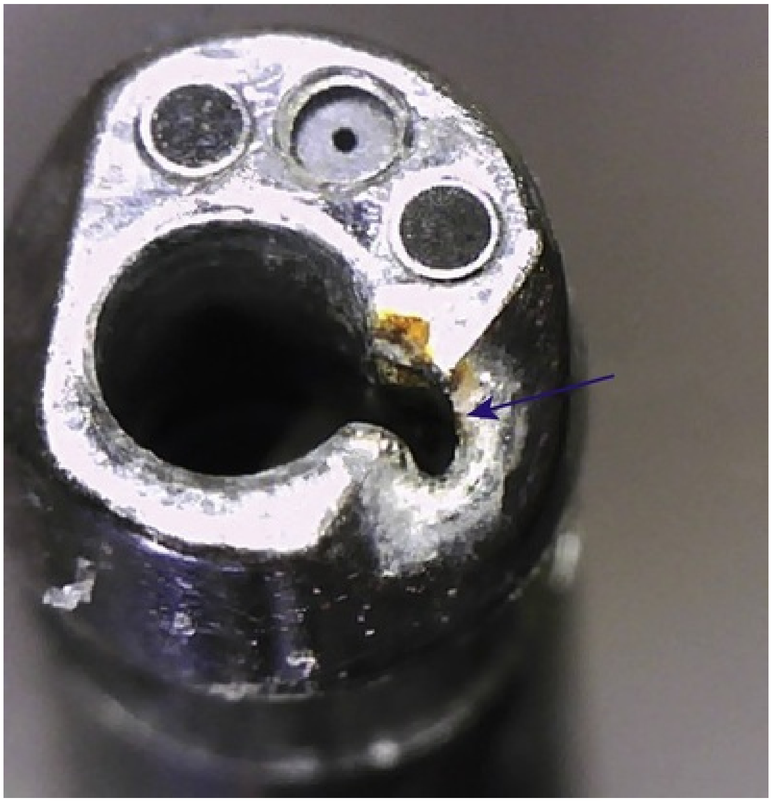

FIG. 13.13 Image of the tip of a flexible ureteroscope that has been damaged by firing of the holmium laser within the working channel *(arrow).*

Ureteroscopes, including the working channel, should be cleaned with warm water and a nonabrasive detergent after each use. Sterilization of ureteroscopes can be performed by using gas (ethylene oxide), soaking in a glutaraldehyde solution, or using the Steris system (Mentor, OH) (Gregory et al., 1988). The Steris system provides automated washing and rinsing of the endoscopes in a peracetic acid solution.

Guidewires

Guidewires are essential to urologic endoscopy. We use them for many portions of these procedures—the establishment of percutaneous or ureteroscopic access, straightening of the ureter, a guide for dilation of the ureter or percutaneous tract, and stent placement. Many types of guidewires are available differing in diameter, rigidity, tip design, materials, and coating. The choice of the most appropriate wire depends on the present task, the patient's anatomy, and upper urinary tract problem being confronted.

The most common design is a solid stainless steel core around which an outer wire is wrapped. Nitinol (nickel-titanium) can be used for inner core construction, and this gives guidewires a kink-resistant, slightly stiffer property. Some newer wires (Zebra wire; Boston Scientific, Natick, MA, and Roadrunner wire, Cook Urological, Spencer, IN) have a nitinol core wire and polyurethane outer layer. These wires are well suited for passage of the ureteroscope as there is less friction of the ureteroscope over the polyurethane, and the stiffer core allows more reliable transmission of the "push" from the urologist to the tip of the ureteroscope. Angling of the wire tip is also possible because of the "memory" quality of the nitinol material. When the outer polyurethane layer is coated with a hydrophilic polymer, these wires become exceptionally slippery. These "glide wires" are incredibly adept at negotiating around impacted ureteral calculi, tortuous ureters, and ureteral strictures. **Hydrophilic-coated wires are too slippery to be reliable safety wires because they can easily slide out of the patient. When these wires are used for initial access, they are exchanged for a standard safety wire through an open-ended catheter.** A new hybrid designed wire (Sensor; Boston Scientific, Natick, MA) incorporating a hydrophilic tip with a polytetrafluoroethylene (PTFE)-coated shaft may serve as both an access and safety wire for difficult access cases.

Guidewires for urology range in diameter from 0.018 to 0.038 inches, the most commonly used being 0.038 inches. Lengths vary from 80 to 260 cm. The most useful length for endourology is 145 cm. The tips of these wires are generally "floppy" for 1 to 3 cm. Bentson and Newton wire designs have flexible tips of up to 15 cm and are seldom used today. Some wires have a movable core that can be partially withdrawn to increase the length of the flexible tip. Other variable characteristics in guidewire construction include the distal tip design and the wire stiffness. The distal tip can be straight, angled, or "J" tipped. The rigidity of the wires can be varied by changing the diameter and design of the inner core wire. Stiffer wires can be useful for straightening out tortuous ureters or displacing a sizeable prostatic lobe.

The choice of the most appropriate guidewire for the current endourologic mission can be the difference between failure and success. Despite all of these advances in wire design and construction, a 0.038-inch–diameter straight, flexible-tip, Teflon-coated stainless steel wire is still an excellent choice for most cases.

Dilation Devices

Ureteral dilation is less necessary for ureteroscopy with the advent of smaller-diameter ureteroscopes. Hudson et al. (2005) determined that the need for dilation was directly related to the diameter of the ureteroscope and was as low as 0.9% for 7.4-Fr diameter scopes. When needed, ureteral dilation can be accomplished passively with indwelling stent placement or actively with dilating catheters or balloons. Ureteral dilating catheters are hydrophilic-coated polyurethane catheters tapered from a 6-Fr tip to 12-Fr shaft and are passed over a wire to dilate the ureter (Gaylis et al., 2000). Ureteral balloon dilators are also passed over a wire, have a low profile of 3 to 8 Fr, and have dilation diameters of 12 to 30 Fr. **Dilation of the ureter beyond 15 Fr is rarely necessary for routine ureteroscopy.** Balloons can have maximum inflation pressures of 8 to 20 atmospheres depending on the design and the balloon material. Zero-tip design ureteral balloon dilators are useful for dilating immediately adjacent to an impacted ureteral calculus. Ureteroscopic balloon dilators are 3 Fr in size, can be inflated to 12 Fr, and are passed directly through the ureteroscope. They are used to dilate under direct vision such as dilation of stenotic infundibula or calyceal diverticular necks. Once inflated, these ureteroscopic balloons cannot be removed through the ureteroscope but must be removed together with the ureteroscope.

Intraluminal Lithotripsy Devices

Intraluminal lithotripsy can be performed with several different modalities. Electrohydraulic lithotripsy (EHL) is widely available worldwide and is cost-effective. Fragmentation of calculi is produced by shock waves from an electric spark generated on the tip of the electrode (Denstedt and Clayman, 1990). Fragmentation of most calculi is good but is less effective for denser calculi compositions such as cystine or calcium oxalate monohydrate. The small, flexible EHL probes can be used with both rigid and flexible ureteroscopes. EHL can cause ureteral trauma because the energy is poorly focused. Although this rarely results in stricture formation, it can hinder visibility. It is also alarmingly easy to damage the ureteroscope when using EHL. For all of these problems, EHL is now rarely used.

Pneumatic lithotripsy devices fragment calculi using mechanical ("jackhammer") energy (Schulze et al., 1993). Fragmentation is very good, and the potential for ureteral injury is low. Unfortunately, the mechanical energy can produce significant stone retropulsion. The rigid probes are limited to use with rigid scopes. There are flexible probes available that can be used with flexible ureteroscopes, but they significantly restrict scope deflection (Zhu et al., 2000).

The pulsed dye laser was the first laser successfully used for intraluminal lithotripsy. This energy is no longer used because of the inability to fragment specific compositions of calculi and the high cost of purchase and maintenance. **The holmium:YAG laser has become the intraluminal lithotripsy energy of choice. It has a wavelength of 2100 nanometers, which is absorbed in 3 millimeters of water, making it very safe for use in urology** (Blomley et al., 1995). Fragmentation is produced by a photothermal reaction with the crystalline matrix of calculi and produces stone dust rather than fragments, effectively removing a moderate volume of the stone (Zagone et al., 2002). The flexible quartz fibers can be used with both rigid and flexible ureteroscopes and are reusable. The holmium laser is effective for any composition of calculi (Bagley and Erhard, 1995; Denstedt et al., 1995; Erhard and Bagley, 1995; Grasso, 1996).

Stone-Retrieval Devices

The essential components of stone-retrieval devices include the control handle, the control wire, the sheath, and the device itself. These instruments have shaft diameters that vary in size from 1.9 to 7.0 Fr. Devices for ureteroscopy are 3.0 Fr or smaller to fit in the working channel while leaving enough room for adequate irrigation. Larger-diameter devices are used for cystoscopic or percutaneous procedures.

Three-pronged grasping forceps are the safest instruments for removing calculi with the flexible ureteroscope. They reliably release stones that are too large to retrieve from the ureter safely. The weaker grasp will merely release the stone if too much force is applied, preventing damage to the ureter. Care not to basket an irretrievable-sized stone is critical when using a flexible ureteroscope without a second working channel. A second working channel permits fragmentation of an unyielding stone trapped within a basket in the other channel. Rigid ureteroscopes with two working channels have this additional degree of safety, allowing the more routine use of baskets for removal of ureteral calculi. Although three-pronged graspers are the safest devices for ureteroscopic stone removal, they are seldom used because of improvements in the design and safety of stone baskets.

Stone baskets are available in helical, flat-wire, and other shapes. Baskets can also vary in the number and type of wires used. Two sheathing materials—PTFE and polyimide—are commonly used for working instruments including stone baskets. A sheath made of polyimide is durable but stiff and limits deflection of the flexible ureteroscope. PTFE does not limit deflection as much as polyimide but is less durable and prone to stretching. Hybrid sheath designs incorporate Teflon at the tip and polyimide in the shaft, maximizing the advantages of each material. Helical baskets can be made with three, four, or double-wire designs with six or more wires. The double-wire designs have improved opening strength, which may facilitate removal of impacted calculi. Other basket designs unwind the dual wires, exposing more wires on the distal end of the basket, making them useful for removing multiple small fragments. Helical baskets have round wires and, unlike flat wire baskets, are safe to rotate within the ureter. They are opened above the stone and pulled down while rotating the basket to engage the stone.

Flat wire baskets are nonhelical and are designed to have larger spaces between the four wires to allow engagement of larger stones. They were initially designed for percutaneous use, where, by filling the calyx when opened, they could more easily engage calyceal stones. They are also useful for biopsy of papillary ureteral tumors (Bagley, 1998).

Several basket designs attempt to combine the safety of three-prong graspers with the solid grasp of baskets, the Graspit and Dakota from Boston Scientific (Natick, MA) and NGage from Cook Urological (Spencer, IN). These tipless devices open at the distal end like three-pronged graspers and are advanced onto the stone, permitting easier disengagement of a calculus that is too large to withdraw from the ureter safely.

The most recent material innovation is the use of nitinol for the basket wires. The soft nitinol wires have memory, maintain their shape, resist kinking, and therefore open more safely and allow disengagement of stones more reliably than stainless steel baskets. The unique qualities of nitinol also enable basket construction in a tipless fashion. These tipless baskets are soft and safe for use in the ureter and can be more fully deployed in a calyx without the interference from the tip, unlike stainless steel baskets.

Retropulsion Prevention Devices

Intraluminal lithotripsy within the ureter can propel the stone proximally (“retropulsion”). The amount of retropulsion depends on the size and location of the stone, the degree of ureteral dilation, and the lithotripsy energy used. Retropulsion of a stone back into the kidney is not a problem and is sometimes desirable. The now renal calculus can be treated with a flexible ureteroscope. However, prevention of retropulsion may be more expeditious and is particularly important for situations in which no flexible ureteroscope is available.

There are several devices designed to prevent retropulsion of ureteral stones (Fig. 13.14): The Stone Cone and LithoCatch (Boston Scientific, Natick, MA), the NTrap (Cook Urological, Spencer, IN), and the Accordian and CoAx (Accordian Medical, Indianapolis, IN) (Eisner and Dretler, 2009; Wang et al., 2011; Wu et al., 2013). The Stone Cone is a 3-Fr device with a distal coil that can be deployed above the stone before fragmentation to help prevent stone migration. After fragmentation of the stone, it can be withdrawn to remove fragments. Any fragments too large to safely remove are left behind because the coil simply unravels around the stone. The NTrap device is a 2.8-Fr device with a meshlike wire basket that deploys perpendicular to the shaft, preventing migration of all but the smallest stone fragments. A unique solution to prevent stone retropulsion was the use of a reverse-thermosensitive gel (Rane et al., 2010). The gel was injected above the stone, conforming to and completely occluding the ureter. The deployment catheter was removed after injection of the gel, preventing hindrance of the ureteroscopic procedure. The gel could then be dissolved by irrigating with cold saline solution. This gel is no longer available, but other similar approaches may be developed in the future.

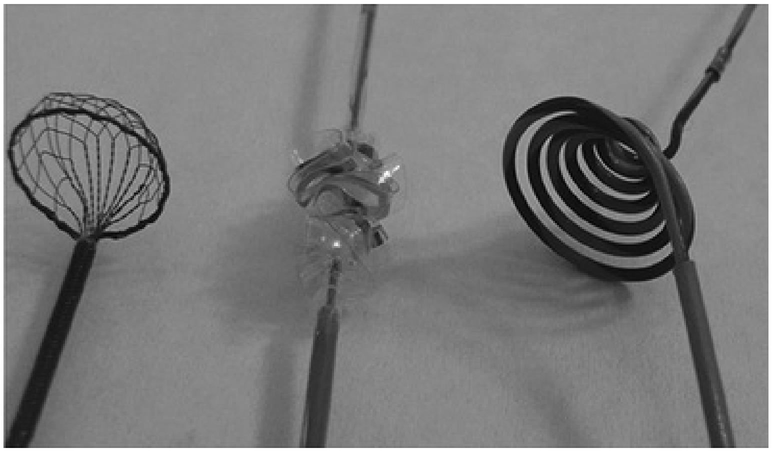

FIG. 13.14 Stone migration devices designed to prevent stone retropulsion during lithotripsy. *From left to right:* NTrap (Cook Medical, Bloomington, IN), Accordion (PercSys, Palo Alto, CA), and Stone Cone (Boston Scientific, Natick, MA).

Miscellaneous Devices

Other devices are available for use during ureteroscopy. Small 3-Fr cup biopsy forceps can be used for biopsy of sessile tumors. A larger biopsy forceps, the

BIGopsy (Cook Urological, Spencer, IN) provides a much more substantial biopsy specimen, which may improve diagnostic yield (Wason et al., 2012). The large forceps requires backloading of the device into the ureteroscope, and it must be removed together with the ureteroscope after the biopsy. Electrodes are available in various shapes including pencil-tip, ball-tip, angled-tip, and straight-tip. These can be used for fulguration and incisional procedures such as endoureterotomy and endopyelotomy.

Ureteral Access Sheaths

Ureteral access sheaths allow repeated access to the intrarenal collecting system without having to replace the working guidewire with each passage of the endoscope (Fig. 13.15). They are available in 11- to 16-Fr sheath outer diameters. Table 13.7 lists the currently available ureteral access sheaths.

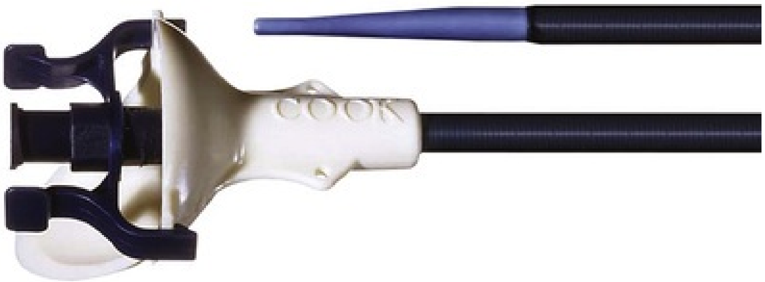

FIG. 13.15 The distal *(top)* and proximal *(bottom)* portions of a typical ureteral access sheath. The distal portion of the internal obturator *(blue)* is tapered. The access sheath is placed over a super-stiff guidewire and the internal obturator is removed before ureteroscope insertion. The proximal end of the obturator accepts a Luer-Lock syringe, facilitating retrograde pyelography.

TABLE 13.7

Characteristics of Currently Available Ureteral Access Sheaths

MANUFACTURER	SHEATH NAME	DILATOR/SHEATH (Fr)	LENGTHS (cm)	UNIQUE FEATURES

In addition to facilitating stone fragment retrieval, access sheaths have been shown to decrease the intrapelvic pressure during ureteroscopy, which may reduce the risk for infectious complications from pyelovenous backflow (Auge et al., 2004). Their primary disadvantage is related to their size and their (small) potential for ureteral injury (Delvecchio et al., 2003; Traxer and Thomas, 2013). Furthermore, the majority of intrarenal stones only require a single passage of the ureteroscope to access and completely fragment the calculi. For these cases, an access sheath is usually unnecessary.

Fluoroscopy Equipment

Fluoroscopy is used for ureteroscopic procedures and is helpful for initial ureteral access, monitoring during endoscopy, and stent placement. Although tables designed for urologic endoscopy with fixed fluoroscopy units are available, mobile C-arm fluoroscopy units are preferable. **C-arm fluoroscopy units allow greater mobility, improved image quality, and less scatter radiation exposure to the surgeon because the x-ray source is below the patient.** Modern C-arm fluoroscopy units incorporate digital enhancement of the image and “last image hold” technology to minimize radiation exposure.

Exposure can also be decreased by using image collimation and pulsed fluoroscopy. The urologist should control the fluoroscopy unit with foot pedal control, which will facilitate the speed of the case and minimize excessive fluoroscopy time. When possible, collimation and pulsed fluoroscopy should be employed to further limit exposure. Several recent "fluoroless" ureteroscopy series have been published calling into question the need for imaging during routine cases (Hsi and Harper, 2013; Olgin et al., 2015).

Ureteroscopy Technique

Preparation for Ureteroscopy

As with cystoscopy, a urinalysis, and urine culture if indicated, should be performed before performing upper-tract endoscopy. Urinary tract infections are treated preoperatively with culture-specific antibiotics. According to the AUA Best Practice Policy Statement, **all patients undergoing upper-tract endoscopy should receive antibiotic prophylaxis. Agents of choice include a fluoroquinolone or trimethoprim-sulfamethoxazole with an aminoglycoside plus or minus ampicillin; a first- or second-generation cephalosporin; or amoxicillin/clavulanate** (Wolf et al., 2008). First- and second-generation cephalosporins are also considered first-line agents in patients undergoing PCNL. In contrast, the EAU's Urological Infections guidelines cite a lack of controlled trials on ureteroscopy (Bonkat et al., 2017). As a result, prophylaxis for low-risk procedures (e.g., simple diagnostic ureteroscopy and treatment of distal ureteral stones) are left to clinician discretion. The EAU recommends prophylaxis with trimethoprim plus or minus sulfamethoxazole; amoxicillin/clavulanate; or a second- or third-generation cephalosporin in patients undergoing percutaneous stone extraction.

Anesthesia can be general (endotracheal or laryngeal mask), regional, or local with sedation (Hosking and Bard, 1996; Vögeli et al., 1993). It is essential to inform the anesthesia provider about the need for the patient to remain still throughout the procedure. Significant patient movement during rigid ureteroscopy can result in ureteral injury or perforation.

Endourologic procedures should be performed in a fully equipped operating room. The urologist should be prepared for any unanticipated problem encountered. In addition to conventional Teflon-coated stainless steel guidewires, angled hydrophilic, nitinol core, and extra-stiff guidewires should be readily available. Dilation devices including dilating catheters, high-pressure balloon catheters, and zero-tipped balloon catheters are standard. Angled catheters that can be reliably rotated or “torqued” are very useful for gaining access beyond impacted calculi, strictures, or tortuous ureters. These include the Imager II catheter (Boston Scientific, Natick, MA) and the Kumpe catheter (Cook Urological, Spencer, IN). The urologist should be very familiar with the endoscopes available and the size of their working channels to choose appropriately sized working instruments when needed (see Tables 13.5 and 13.6). The largest working channels of most of the fiber-optic rigid ureteroscopes are just over 3 Fr, so devices 3 Fr or less are appropriate. A variety of additional flexible and semirigid ureteroscopes should also be kept ready to ensure availability of appropriately functioning endoscopic equipment to treat pathology regardless of location in the upper urinary tract. Table 13.8 lists items commonly needed items for successful ureteroscopy.

TABLE 13.8

Common Supplies for Ureteroscopy

URETEROSCOPES

- Rigid
  - 7 Fr or smaller semirigid ureteroscope
  - Larger ureteroscope with straight working channel (optional)
- Flexible
  - 7.5 Fr
  - 8.6 Fr or larger
  - Secondary deflection or exaggerated deflection–capable ureteroscope

DISPOSABLE SUPPLIES

- Guidewires
  - 0.038 Angled hydrophilic
  - 0.038 Straight Teflon coated
  - 0.038 Nitinol core, polyurethane coated
  - 0.038 Extra-stiff
- Irrigation
  - Power irrigation device
  - High-pressure working port seal
- Stone-retrieval devices (3.0 Fr or smaller)
  - Helical basket
  - Tipless basket
  - Three-prong grasping forceps or equivalent
- Catheters
  - Dual-lumen catheter

- 6- to 12-Fr Dilating catheter
- 5-Fr Open-ended catheter
- 5-Fr Angled-tip torque-able catheter

Dilation devices
- High-pressure ureteral dilating balloons (5–7 mm)
- “Zero-tip” ureteral dilating balloon

Biopsy devices
- 3-Fr Cup biopsy
- Flat-wire basket
- BIGopsy (optional)

Ureteral stents
- 5- to 7-Fr, 20- to 28-cm, double-pigtail

INTRALUMINAL LITHOTRIPSY DEVICES

Holmium laser
Pneumatic (optional)
Electrohydraulic (optional)

Accessing the Ureter

The patient is placed in the cystolithotomy position. If a longer rigid ureteroscope is being used, the contralateral leg is elevated to allow for the easier introduction of the ureteroscope. With the advent of improved flexible ureteroscopes, most rigid ureteroscopy is confined to the ureter below the iliac vessels, and shorter rigid ureteroscopes can be routinely used decreasing interference from the contralateral leg.

Cystoscopy is performed to inspect the bladder fully and place a safety guidewire. Usually, a simple 0.038-inch–diameter flexible-tip Teflon-coated guidewire is sufficient. A safety wire is useful during rigid ureteroscopy, to maintain access and allow placement of a ureteral stent if any problems are encountered. Care must be taken when trying to gain access around an impacted stone as you can easily perforate the ureter. Manipulation of the wire around the stone may require the use of an angled hydrophilic-coated wire, an angled torquable catheter, or both. If a guidewire cannot be safely passed beyond the stone, direct inspection of the ureter up to the stone with the rigid ureteroscope will permit passage of the wire under direct vision. Once access above the stone is achieved, the hydrophilic wire is exchanged for a more secure standard 0.038-inch diameter Teflon-coated guidewire. If there is any suspicion about possible infection above the stone, an open-ended catheter should be passed over the wire to aspirate the renal pelvis. The hydronephrosis can be decompressed to permit irrigation, and if the fluid appears turbid, a stent is placed and the ureteroscopy postponed until treatment of the infection. Before proceeding with the ureteroscopy, the bladder is drained to permit the accumulation of irrigation fluid during ureteroscopy and minimize buckling of the flexible ureteroscope into the bladder (Fig. 13.16).

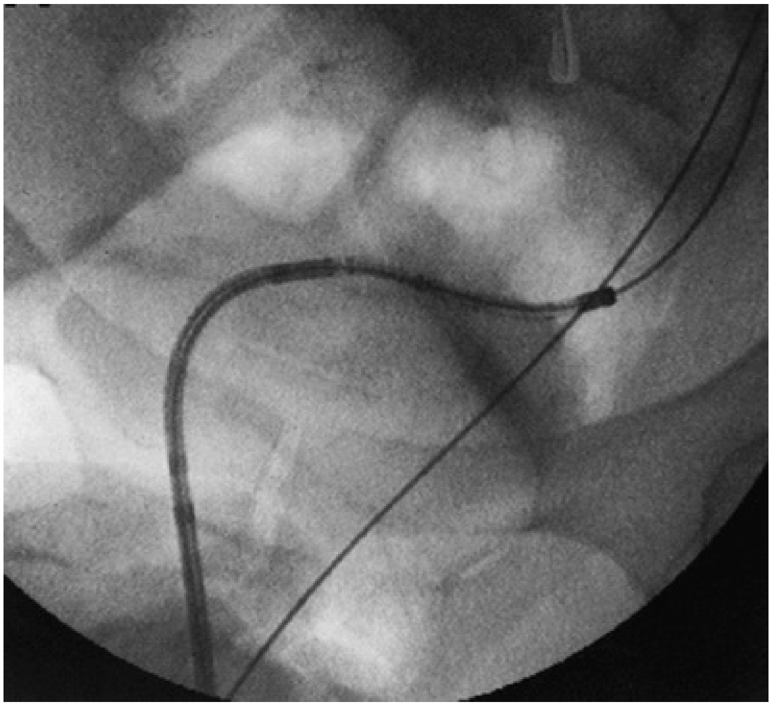

FIG. 13.16 The bladder should be emptied before flexible ureteroscope passage to prevent buckling of the instrument within the bladder if resistance is met at the ureteral orifice.

Semirigid Ureteroscopy Technique

Flexible ureteroscopes better accommodate the natural tortuosity of the ureter, and their deflection provides better access to the intrarenal collecting system than semirigid ureteroscopes. For these reasons, semirigid ureteroscopy is generally limited to the ureter distal to the iliac vessels.

Semirigid ureteroscopy begins with cystoscopic placement of a safety guidewire in the ureter. The ureteroscope is then introduced through the urethra, into the bladder under direct vision usually with the aid of the video camera. By visually following the guidewire, the ureteral orifice is easily identified. By maneuvering the tip of the ureteroscope next to the guidewire posterolaterally, the wire can be elevated, thereby propping the ureteral orifice open to allow scope passage. If necessary, an additional wire can be passed through the ureteroscope into the ureter just beyond the intramural segment. The ureteroscope is then rotated until it is directly between the two wires, which will hold the orifice widely open for entry of the scope (Fig. 13.17). Once the ureteroscope is through the intramural ureter, the additional guidewire can be removed. This technique is also useful when negotiating through tortuous segments of the ureter and above the iliac vessels.

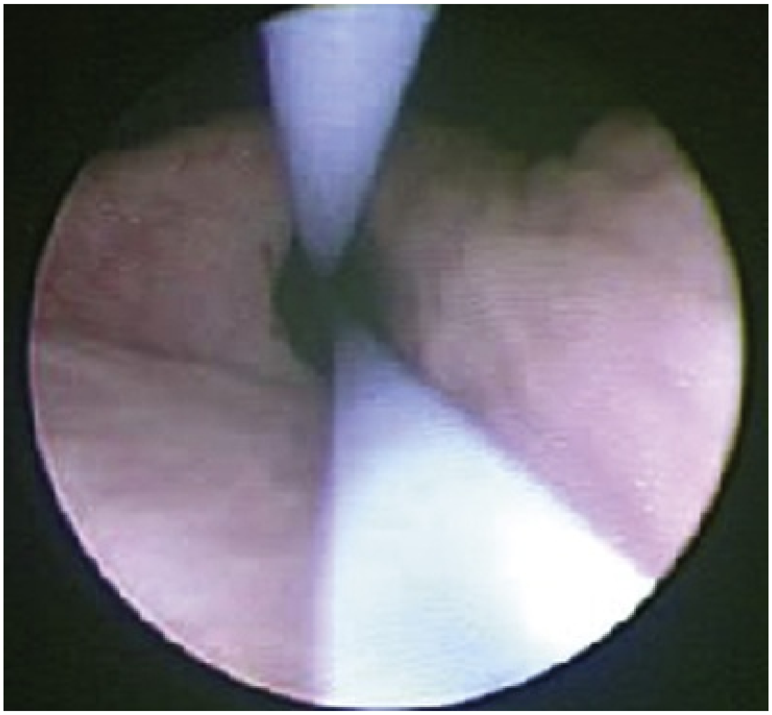

FIG. 13.17 Semirigid ureteroscope passage between two wires. After safety wire placement *(bottom wire)*, a second wire *(top wire)* is passed through the working channel and up the ureter using fluoroscopic guidance to “tent open” the ureteral orifice. The ureteroscope is then gently advanced between the wires until ureteral access is achieved.

If the intramural ureter is too tight to allow safe passage of the ureteroscope, a balloon catheter can be used to dilate the orifice. A 4-mm–diameter balloon is sufficient. If there is a stricture beneath a stone that prevents safe visualization and lithotripsy, dilation beneath the stone is performed with a zero-tip balloon catheter. This catheter can be passed over the safety wire immediately below the stone so dilation of the stenotic segment can be achieved. The ureteroscope can then be safely introduced and the stone visualized. If a ureteral stone is impacted, it can be helpful to gently manipulate it with the tip of the ureteroscope proximally out of the traumatized area of ureter for improved visibility and safer lithotripsy. If this is not possible, the holmium laser energy can be used in a “drill and core” technique. Using this method, we ablate the central portion of the stone, and the outer shell of the stone will partially protect the ureteral wall. The later collapsed outer shell can then be safely fragmented. Ureteral stones can be “dusted” until no fragments are greater than 2 mm or cleaved until the fragments are small enough to be easily removed with a helical basket. A stent is placed and generally left for 3 to 7 days.

Flexible Ureteroscopy Technique

After the guidewire is placed in the ureter, the cystoscope is removed, and a dual-lumen catheter is passed over the wire. This catheter is 10 Fr, which will gently dilate the ureteral orifice and allow placement of a second, working wire. The flexible ureteroscope is then passed in a monorail fashion over the taut working wire to the point of the pathology. Dilation of the ureteral orifice with the dual-lumen catheter is usually sufficient to permit passage of the flexible ureteroscope.

The working channel of flexible ureteroscopes is not centrally located, so the tip of the ureteroscope will be eccentrically positioned relative to the guidewire. If the flexible ureteroscope does not pass the ureteral orifice, it should be rotated 90 to 180 degrees on the guidewire to better position the tip of the ureteroscope relative to the ureteral orifice. If difficulty passing the flexible ureteroscope through the ureteral orifice is still encountered, a dilating catheter (Nottingham) or a dilating balloon catheter can be used to dilate the ureteral orifice. **Formal ureteral dilation is reported in most ureteroscopy series to be needed in 8% to 25% of patients and has decreased with the advent of smaller-diameter flexible ureteroscopes** (Elashry et al., 1997; Grasso and Bagley, 1998; Tawfiek and Bagley, 1999). However, a more recent study of 11,885 patients at 114 centers in 32 countries found a ureteral dilation rate of 33.7%, indicating it remains a common practice worldwide (de la Rosette et al., 2014).

Traditionally, a safety wire has been used during upper-tract endoscopy to maintain access throughout the procedure, allowing for ureteral stent placement should injury to the ureter occur. However, with continued miniaturization of ureteroscopes and more widespread adoption of upper-tract endoscopic techniques, the utility of the safety wire has been called into question (Dutta et al., 2016).

If the passage of the flexible ureteroscope is difficult in the absence of any significant ureteral stricture or another source of obstruction, the use of a nitinol core polyurethane-coated guidewire may be helpful. As previously discussed, these stiffer, smoother wires enable more efficient transmission of the push from the urologist to the tip of the ureteroscope.

The basic movements of the flexible ureteroscope include deflection, rotation, and advancing and retreating the ureteroscope. The reticle of the flexible ureteroscope marks the plane of deflection, and rotation of the ureteroscope is often necessary to align this plane of deflection in the direction desired. **Failure to adequately rotate the ureteroscope is the most common mistake of the novice ureteroscopist.** Irrigation through the ureteroscope should be provided with a pressurized irrigation bag, pump, or handheld syringe. Irrigation must be well controlled and only delivered when needed to clear the visual field. **Normal saline should be used to prevent accumulation and absorption of a hypotonic solution and resultant "TUR syndrome."**

When using the holmium laser, it is essential to pass the laser fiber through a straightened flexible ureteroscope—confirmed fluoroscopically—to prevent damage to the working channel. Once the fiber is advanced beyond the tip, the ureteroscope can be deflected appropriately. The most commonly used sizes of holmium laser fibers include the 365-micron fiber and the 200-micron fiber. When significant deflection of the ureteroscope is needed, the more flexible 200-micron fiber is preferred, as it limits the deflection of the ureteroscope less than larger fibers. The tip of the fiber must be in contact with the stone during treatment because the holmium laser energy is absorbed in 3 mm of water. **The holmium laser can damage the ureteroscope, the guidewire, and the ureteral wall. These problems can be avoided by not activating the laser unless the tip of the fiber is seen in contact with the stone** (Beaghler et al., 1998). Additionally, if the helium-neon aiming beam is not visible, the laser should not be activated, as this may be an indication of fiber damage. Firing the holmium laser through a broken fiber can cause significant damage to the ureteroscope.

Once the pathology has been adequately addressed, a ureteral stent is usually placed and left indwelling for 3 to 5 days. Postoperative pain management can be facilitated with the use of a COX-2 inhibitor, an alpha-adrenergic blocker, or both (Nazim and Ather, 2012).

Key Points: Ureteroscopy

- Semirigid ureteroscopy is used below the iliac vessels and flexible ureteroscopy above.
- Semirigid ureteroscopes with two working channels permit better irrigation and the added safety of being able to pass a lithotripsy device through one channel when needing to fragment a stone engaged in a basket in the other channel.
- Flexible ureteroscopes must be straight when passing a laser fiber, or the working channel will be damaged.
- The golden rule of safe laser lithotripsy: “Do not step on the pedal if you cannot see the tip of the fiber in contact with the stone.”
- Stone baskets made of nitinol maintain their shape, resist kinking, and allow disengagement of stones more reliably than stainless steel baskets.
- Ureteral access sheaths facilitate repeated passage of flexible ureteroscopes and decrease the intrapelvic pressure during ureteroscopy.
- Mobile C-arm fluoroscopy is preferred because of greater mobility, improved image quality, and less scatter radiation exposure to the surgeon compared with urology tables with fixed fluoroscopy units.
- A routine preoperative antibiotic should be given to all patients undergoing ureteroscopy.
- Normal saline should be used as irrigation during ureteroscopy to prevent absorption of a hypotonic solution.

Conclusion

Over the past 150 years, tremendous advances have been made in endoscope design revolutionizing urologic surgery. Visualization of both the upper and lower urinary tracts is now routinely performed with rigid and flexible endoscopes. A variety of urologic conditions can be evaluated efficiently with minimal discomfort in the office by flexible cystoscopy. A wide array of benign and malignant pathologies affecting the bladder and urethra can be managed transurethrally with rigid cystourethroscopes in the operating room with limited morbidity. Improvements in flexible ureteroscopes, working instruments, and endoscopic techniques have significantly improved our ability to effectively treat upper urinary tract problems as well. With continued innovation and refinement, the role of ureteroscopy in the treatment of complex intrarenal calculi, ureteral obstruction, and upper-tract tumors should continue to grow.

Fundamentals of Laparoscopic and Robotic Urologic Surgery

Roshan M. Patel MD, Kamaljot S. Kaler MD, Jaime Landman MD

More than 100 years ago the “father of modern medicine,” Sir William Osler, challenged surgeons to perpetually refine their craft, stating, “Diseases that harm require treatments that harm less.” In pursuit of this noble goal, the urologists of the 20th century brought us great achievements in our field; however, in the past 30 years, in particular, the specialty of minimally invasive urology has become predominant. The earliest techniques that laid the foundation for modern laparoscopic and robotic urologic procedures were developed at academic institutions throughout the world and have continuously been validated and improved. Subsequently, an increasing number of multi-institutional studies have emerged comparing laparoscopic and robotic procedures with their open surgical counterparts and showing equivalent efficacy and acceptable efficiency as well as the distinct advantages of decreased postoperative pain, improved cosmesis, expedited recovery, a shorter hospital stay, and, as techniques evolve and mature, in many cases, lower cost. Indeed, it has become increasingly clear that the objectives of many open urologic surgeries even for the most complex cases, be it of the adrenal gland, kidney, ureter, bladder, prostate, or lymph nodes, can now be achieved with minimally invasive surgery with less patient injury and suffering. Therefore, whereas open surgery has had a steadily diminishing role in the treatment of urologic diseases, laparoscopic and robotic surgery have moved into the mainstream of urologic surgery. Knowledge of the required principles and techniques is essential for the practicing urologist. This chapter provides a basic foundation of knowledge on which the aspiring minimally invasive urologist can build.

Preoperative Preparation

Patient Selection and Contraindications

Careful patient selection and identification of possible relative and absolute contraindications to laparoscopic and robotic procedures are vital to a successful outcome. A meticulous history, focusing on prior surgeries, and physical examination, detailing the location and extent of all abdominal scars, are the initial steps in patient evaluation.

Age- and health-based laboratory studies, an electrocardiogram, and a chest radiograph should be obtained according to the same criteria established for any other significant surgical procedure undertaken with general anesthesia.

In patients with severe chronic obstructive pulmonary disease (COPD), further studies (i.e., arterial blood gases and pulmonary function tests) are required because of the physiologic effects of the CO_2 pneumoperitoneum. Cardiac arrhythmias should be evaluated and treated preoperatively because hypercarbia and the resulting acidosis from the pneumoperitoneum may have adverse effects on the myocardium, thereby exacerbating any preexisting myocardial instability.

Contraindications to laparoscopic surgery include uncorrectable coagulopathy, intestinal obstruction unless there is an intention to treat, significant abdominal wall infection, massive hemoperitoneum or hemoretroperitoneum, generalized peritonitis, and suspected malignant ascites. Select circumstances in which laparoscopic and robotic procedures are being contemplated necessitate careful risk-benefit analysis and detailed and specific informed consent with the patient. The following conditions may portend potential difficulties with a laparoscopic or robotic approach.

Morbid Obesity

Laparoscopic and robotic procedures in morbidly obese patients are technically challenging. Difficulties may include inadequate length of instruments, decreased range of motion of trocars and instruments, need for higher pneumoperitoneum pressures to elevate the abdominal wall, and poor anatomic orientation owing to excessive amounts of adipose tissue. Traditionally, these difficulties translated into a higher rate of associated complications (Aboumarzouk et al., 2012; Anast et al., 2004; Mendoza et al., 1996; Parker et al., 2008). However, in comparison with open surgery, it has been found that the laparoscopic approach to renal and adrenal procedures actually has several advantages. Studies have shown for laparoscopic adrenalectomy and nephrectomy in obese patients that the laparoscopic group had significantly superior outcomes regarding blood loss, resumption of oral intake and ambulation, narcotic analgesic requirements, median hospital stay, and convalescence compared with the open approach (Fazeli-Matin et al., 1999; Fugita et al., 2004; Kapoor et al., 2004; Shuford et al., 2004). These findings have been confirmed for complicated procedures such as laparoscopic and robotic partial nephrectomy (Colombo et al., 2007; Isac et al., 2012; Romero et al., 2008) and laparoscopic nephroureterectomy (Brown et al., 2008).

With regard to laparoscopic and robotic radical prostatectomy in obese men, it has been found that, although the operation can be performed without compromising pathologic outcomes, obese patients have a greater risk of perioperative complications (26% vs. 5%) (Ahlering et al., 2005). Similarly, with robotic cystectomy there was found to be a small but statistically significant risk of complication in those with a body mass index (BMI) over 30 (Johar et al., 2013). Surgeon and institutional experience should guide patient selection in morbidly obese patients because laparoscopic and robotic procedures in morbidly obese patients are certainly more challenging and should be performed later in the surgeon's career.

Extensive Prior Abdominal or Pelvic Surgery

When extensive intra-abdominal or pelvic adhesions are suspected, careful consideration must be given to the possible site of Veress needle insertion as well as to obtaining open access with a Hasson-style cannula. **The Palmer point (subcostal in the midclavicular line on the left side) is the preferred site for Veress needle insertion when extensive intra-abdominal adhesions are suspected** (Palmer, 1974). Alternatively, in patients with suspected adhesions, a retroperitoneal approach may be preferable to a transperitoneal approach, or the procedure can be initiated retroperitoneally and the peritoneum entered via the retroperitoneal access (Cadeddu et al., 1999).

Pelvic Fibrosis

Pelvic fibrosis caused by previous peritonitis, pelvic surgery, or extensive endometriosis may constitute a severe technical challenge to the laparoscopic and robotic surgeon when surgery of the lower urinary tract is indicated. Similar problems may be encountered when trying to perform pelvic lymph node dissection in patients who have a hip prosthesis; leakage of the polymethyl methacrylate cement can create a dense inflammatory reaction and fibrosis in the adjacent pelvis (Cooper et al., 1997).

Organomegaly

Known or preoperatively diagnosed organomegaly (e.g., hepatomegaly or splenomegaly) necessitates a cautious approach when obtaining the pneumoperitoneum. The site of Veress needle insertion must be chosen at a safe distance from any enlarged organs, or, preferably, open access with the Hasson cannula may be considered.

Ascites: Benign Cause

Patients with severe ascites are under increased risk of injury to the bowel because of closer proximity of bowel loops to the anterior peritoneum. In addition, a watertight wound closure is required, and a firm wound dressing should be applied to prevent prolonged postoperative leakage.

Pregnancy

Any surgery in the gravid female should be carefully considered with regard to the overall risk/benefit ratio. If surgery is indicated, initial access to the abdomen must be obtained at a safe distance from the fundus of the gravid uterus. Therefore trocar placement is usually performed more cephalad on the abdominal wall, depending on the fundus of the uterus. The left upper quadrant in the subcostal midclavicular line (i.e., Palmer point) is often the preferred site of access. Prolonged intra-abdominal pressures of 15 mm Hg or greater may result in hypotension because of significantly reduced venous return because the vena cava is already mechanically compromised by the enlarged uterus. Prolonged CO_2 pneumoperitoneum, which may result in maternal hypercarbia and acidosis with subsequent adverse effects on the fetus, should be avoided. Accordingly, a working pneumoperitoneum of 8 to 12 mm Hg is recommended in the pregnant patient. **The second trimester is a preferred time for necessary surgery, given the completion of fetal organogenesis and reduced chance of inducing labor.**

As pregnancy progresses beyond the 20th week, the possibility of performing laparoscopic procedures decreases significantly, correlating with the increasing size of the gravid uterus. Laparoscopic nephrectomy and adrenalectomy have been successfully accomplished in pregnant women (Nezhat et al., 1997; O'Connor et al., 2004; Sainsbury et al., 2004).

Hernia

A diaphragmatic hernia may result in leakage of a significant amount of CO_2 into the mediastinum, which, although rarely noted, may eventually result in clinical problems such as respiratory compromise or cardiac tamponade (e.g., pneumopericardium) (Knos et al., 1991).

Any evidence of uncorrected or surgically corrected umbilical hernia or abdominal wall hernia should rule out these sites for obtaining a pneumoperitoneum.

Iliac or Aortic Aneurysm

Significant aneurysms warrant evaluation by the vascular surgeon. If the aneurysm does not require immediate surgical correction, insertion of the Veress needle should be performed in the left upper quadrant to stay well away from the area of the aneurysm. Of course, open access with the Hasson technique can be used alternatively. Insertion of accessory trocars must be done under strict endoscopic control to avoid the area of the aneurysm.

Bowel Preparation

For extraperitoneoscopy and retroperitoneoscopy, no bowel preparation is typically necessary. Similarly, for transperitoneal laparoscopic or robotic procedures *not* involving the use of bowel segments for urinary tract reconstruction, a mechanical bowel preparation is typically not necessary. A recent large-scale propensity score-matched analysis demonstrated no benefit for mechanical bowel preparation in operative time, postoperative stay, or overall complications for patients undergoing laparoscopic nephrectomy (Sugihara et al., 2013a). Likewise, the same group found no benefit to mechanical bowel preparation in patients undergoing laparoscopic radical prostatectomy in terms of complications, operative time, and postoperative length of stay (Sugihara et al., 2013b).

The need for a full mechanical and antibiotic bowel preparation is subject to question and becomes an issue only if one anticipates encountering dense intra-abdominal adhesions or if the surgery involves entering the bowel. However, emerging literature suggests no benefit to a full mechanical bowel preparation for patients undergoing radical cystectomy with creation of ileal conduit or orthotopic neobladder (Hashad et al., 2012; Large et al., 2012; Raynor et al., 2013).

Enhanced Recovery After Surgery Protocols

Enhanced recovery after surgery (ERAS) was developed in Europe in 2001 by a group of academic surgeons (Fearon et al., 2005). It is a multimodal and multidisciplinary approach to resolve issues that delay recovery and cause complications. Elements of ERAS programs include guidelines based on evidence-based modern care changes from overnight fasting to avoiding solid food 6 hours before surgery, carbohydrate drinks 2 hours before surgery, management of fluids to seek balance rather than large volumes of intravenous fluids, early removals of drains and tubes, early mobilization, and the consumption of food and drink on the day of operation. These protocols have resulted in shorter hospital stays by 30%, a reduction in complications by 50%, and a decrease in readmission rates, thus reducing healthcare costs (Lemanu et al., 2014; Ljungqvist et al., 2017). There is accumulating evidence supporting the use of ERAS programs in cystectomy patients, and further high-quality prospective multicenter studies to tailor different elements of ERAS protocols in minimally invasive urologic surgery are necessary (Azhar et al., 2016). Importantly, as changes to existing protocols are made, a key emphasis should be placed on the collaboration between surgery and anesthesia.

Preparation of Blood Products

Serum type and screen are sufficient for laparoscopic and robotic procedures with a low chance of major hemorrhage. Procedures such as laparoscopic radical nephrectomy and nephroureterectomy have a low rate of transfusion (3% to 12%), with an estimated average blood loss in the range of 106 to 255 mL (Dunn et al., 2000; Jeschke et al., 2000; Ono et al., 1999; Shalhav et al., 2000). Similarly, the transfusion rate with laparoscopic or robotic radical prostatectomy is low (2.5% at experienced centers) (Ahlering et al., 2004; Guillonneau and Vallancien, 2000).

More extensive laparoscopic robotic procedures (e.g., partial nephrectomy, radical cystectomy, radical nephrectomy with inferior vena cava thrombectomy), especially early in one's experience, should be managed like any other major open surgical procedure, with packed red blood cells available before surgery. With greater experience, a type and screen may suffice for certain more extensive procedures (e.g., partial nephrectomy) because the risk for transfusion is low (6% to 7%) (Ghani et al., 2014).

Key Points: Preoperative Preparation

- Careful patient selection and identification of contraindications for laparoscopic and robotic procedures are vital for successful outcomes. A meticulous past history, focusing on prior surgeries, and physical examination, detailing the location and extent of all abdominal scars, are the initial steps in patient evaluation for minimally invasive surgery.
- Contraindications to laparoscopic or robotic surgery include uncorrectable coagulopathy, intestinal obstruction unless treatment is intended, significant abdominal wall infection, massive hemoperitoneum or hemoretroperitoneum, generalized peritonitis, and suspected malignant ascites.

Operating Room

Setup of the Operating Room

The operating room has to provide enough space to accommodate all necessary personnel and the equipment required by the surgeon and the anesthesiologist. Positioning of equipment, surgeon, assistants, nurses, anesthesiologist, and other support staff should be clearly defined and established for each laparoscopic or robotic case. All equipment must be fully functional and in operating condition before any laparoscopic or robotic procedure is started (Box 14.1). A separate tray with open laparotomy instruments must be ready for immediate use in the event of complications or problems necessitating emergent open surgery.

Box 14.1

Instrumentation Checklist for Making a Skin Incision for Obtaining the Pneumoperitoneum

1. Irrigation-aspiration unit is working.
2. Electrosurgical unit is working.
3. CO_2 tank is full, with extra CO_2 tank in the room.
4. Camera is white balanced, and light source is working.
5. Insufflation is checked for flow and response to kinking of the tubing.
6. Veress needle is checked for flow and proper tip retraction.

Patient Positioning

Positioning of the patient depends primarily on the procedure to be performed. In the supine position the arms can be tucked snugly at the sides or rest on specially designed sleds. In the Trendelenburg or lateral position, tape and security belts applied across the chest and thighs provide safe and stable positioning of the patient. In the lateral position, all bony prominences in contact with the table must be carefully padded; likewise, the point of contact between any of the positioning straps and the hip or shoulder should be padded. In the lateral position, the bottom leg is flexed approximately 45 degrees while the upper leg is kept straight; pillows are placed between the legs as a cushion and to elevate the upper leg so that it lies level with the flank, thereby obviating any undue stretch on the sciatic nerve. Pads should be placed between the table and the knee and ankle of the lower leg because these are high-pressure areas. In the lateral decubitus position an axillary roll should be used. Application of an active warming system may prevent hypothermia if a lengthy laparoscopic procedure is anticipated.

A host of new advances in padding and table-mounted accessories are now available, but none has been conclusively demonstrated to significantly reduce pressure on the patient's flank in the lateral position. Researchers at the University of California, Irvine, showed that women have significantly lower interface pressures than men (Deane et al., 2008). A BMI greater than or equal to 25, use of a kidney rest, and full-table flexion as opposed to half-table flexion were associated with increases in interface pressure; of these, **use of the kidney rest was believed to be the most detrimental, and its use beyond 20 to 30 minutes was discouraged.** Therefore male patients with a BMI of 25 or higher undergoing laparoscopic surgery in the lateral position with the kidney rest elevated and the table completely flexed are at highest risk of developing rhabdomyolysis from flank pressure. In this study the unaugmented operating table mattress was superior to egg crate or gel padding as an augmenting surface material; egg crate padding was equal or superior to the more expensive gel padding.

Table-mounted accessories for all major commercial operating room tables aid in safely and effectively positioning patients in the lateral decubitus position and in the prone position. For laparoscopic or robotic procedures on the pelvis, the patient can be placed in Trendelenburg position with the legs on split-leg positioners (Fig. 14.1A) or in Allen stirrups (Fig. 14.1B). **Shoulder supports or braces should never be used in this position because of the risk of brachial nerve injury.**

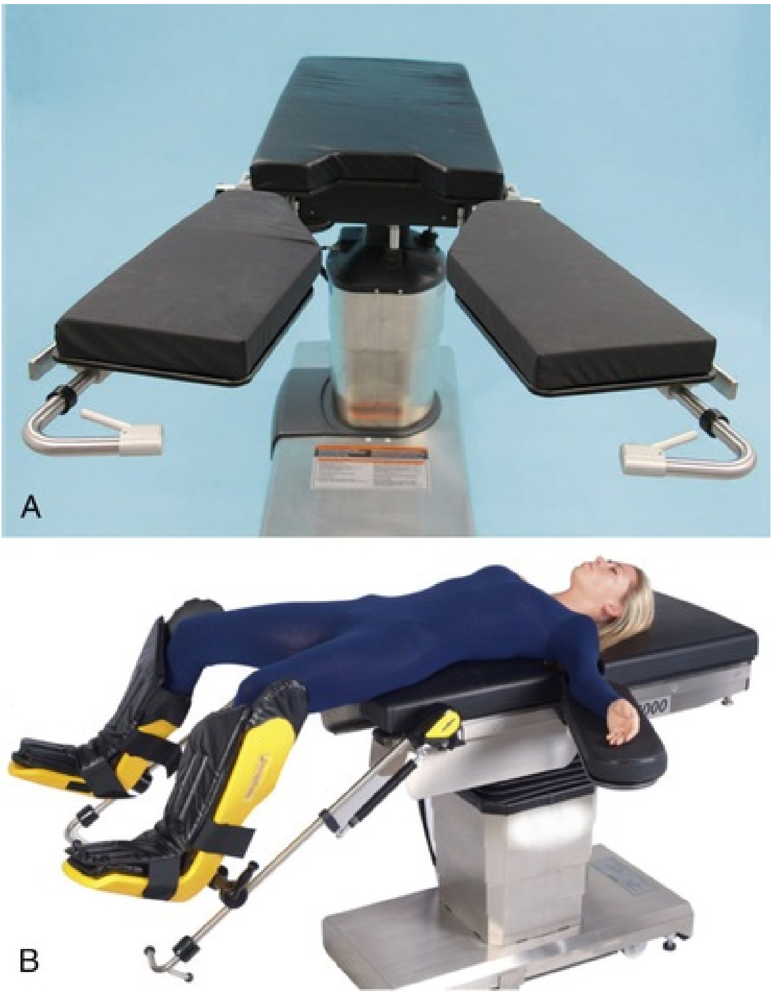

FIG. 14.1 (A) Split-leg positioners. (B) Allen stirrups.

Prophylaxis and Other Preparations

Pneumatic compression stockings can be applied for antiembolic prophylaxis. In addition, the administration of 5000 units of subcutaneous heparin preoperatively is an option. In higher-risk patients, such as the morbidly obese, both may be considered and their use can be continued postoperatively (see the discussion of early postoperative complications). Before laparoscopic or robotic procedures, placement of a Foley catheter allows for accurate measurement of urine output, decompresses the bladder to improve visibility and working space, and reduces the risk of injury with pelvic procedures. Similarly, when needed, a nasogastric or orogastric tube can be inserted to improve the working space available in the upper abdomen.

Strategic Placement of Operative Team and Equipment

Standard Laparoscopic Carts

Traditionally, the mandatory hardware for laparoscopic procedures (monitor, light source, insufflator) is located on carts or towers that are built in the operating room and adapted to various types of surgical procedures and approaches (eFig. 14.2A). The main laparoscopic cart should contain the insufflator, light source, camera controls, and any recording device. Ideally, the insufflator should be placed at the surgeon's eye level to allow continuous monitoring of the CO_2 pressure.

EFIG. 14.2 (A) A standard laparoscopic cart. (B) An integrated laparoscopic vision system.

Integrated Endoscopy Systems

More recently, most major manufacturers of endoscopy equipment offer “integrated” systems that consist of flat panel displays and equipment towers mounted on adjustable ceiling booms (eFig. 14.2B). This allows the mobile display monitors to be suspended over the patient and placed directly in front of the surgeon at any height or angle. This feature may reduce eye and body strain. Furthermore, the tower containing the light source, camera system, and insufflator can be placed in any area around the patient depending on the operation at hand.

Robotic Systems

Currently the only robotic surgical system in widespread use for laparoscopic surgery is the da Vinci Robotic System (Intuitive Surgical, Sunnyvale, CA; Rassweiler et al., 2017). The three major components of the system are the robotic tower (i.e., patient-side cart) to which are attached the instruments that are mechanically manipulated within the patient; a surgeon's console, which is the workstation at which the surgeon sits to manipulate the robotic instruments; and finally the ancillary vision cart, which supports a flat screen monitor, an insufflator, a light source, and components of the camera system (eFig. 14.3). Additional monitors can be linked with the robotic system and used for the assistant and support staff image viewing. The newest generation of the robotic surgical system (da Vinci Xi) offers several advantages over the older Si system. First, the da Vinci Xi uses an 8-mm HD camera that can be placed in any of the four ports, which is important for multiquadrant procedures. Second, the boom-mounted system allows the surgical cart to be placed at any position around the patient, and optimal configuration is achieved with the laser targeting system. Third, the redesigned arms are much finer, which allows for more flexible port placement with less arm collisions during the procedure. Last, updated robotic technology also allows for the use of single-port platforms (e.g., SP 1098 platform), which can overcome the suboptimal ergonomics with clashing instruments in single-site surgery.

EFIG. 14.3 The da Vinci Xi Robotic System (Intuitive Surgical, Sunnyvale, CA) with dual surgeon console. (Copyright 2018 Intuitive Surgical, Inc.)

Placement of the Operative Team for Laparoscopic Procedures

Transperitoneal Procedures in the Upper Abdomen

Laparoscopic.

For transperitoneal laparoscopic renal and adrenal surgical procedures, the patient is positioned in a modified lateral decubitus position. The surgeon and assistant usually stand in front of the abdomen with the patient in the lateral decubitus position (i.e., for a left nephrectomy the surgeon and assistant stand on the right side of the operating table). The instrument table and the scrub nurse are best located on the opposite side of the patient near the foot of the bed so that instruments can be handed to the surgeon over the table (Fig. 14.4A). Incoming lines from insufflators, suction and irrigation, and electrosurgical devices enter from the contralateral side of the table or from the ipsilateral head of the table. Additional instruments (e.g., laparoscopic ultrasound probe) may be moved to the operating table depending on the surgeon's needs, as well as on the availability of space.

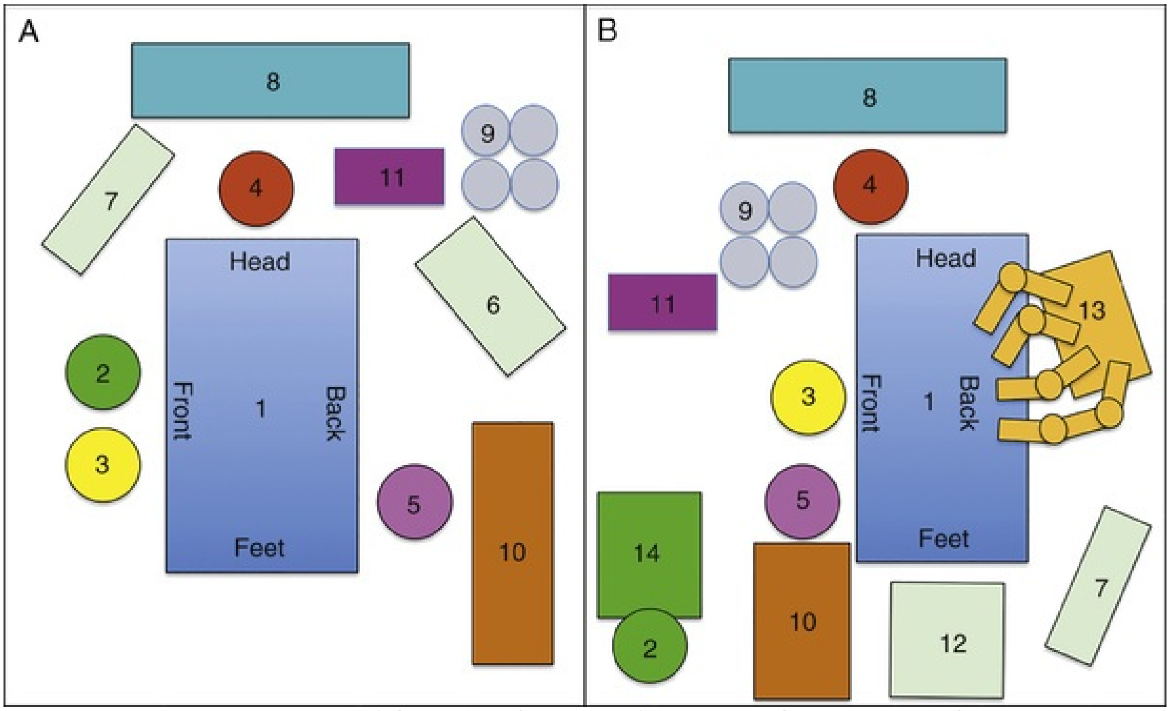

FIG. 14.4 Placement of the operative team for transperitoneal procedures in the upper abdomen. (A) Laparoscopic procedure. (B) Robotic procedure. *1,* Operating table; *2,* surgeon; *3,* assistant; *4,* anesthesiologist; *5,* scrub assistant; *6,* laparoscopic cart or tower; *7,* auxiliary video monitor; *8,* anesthesia equipment; *9,* suction and irrigation unit; *10,* scrub assistant's instrument table; *11,* electrocautery unit; *12,* ancillary vision cart; *13,* robotic tower; *14,* surgeon's console.

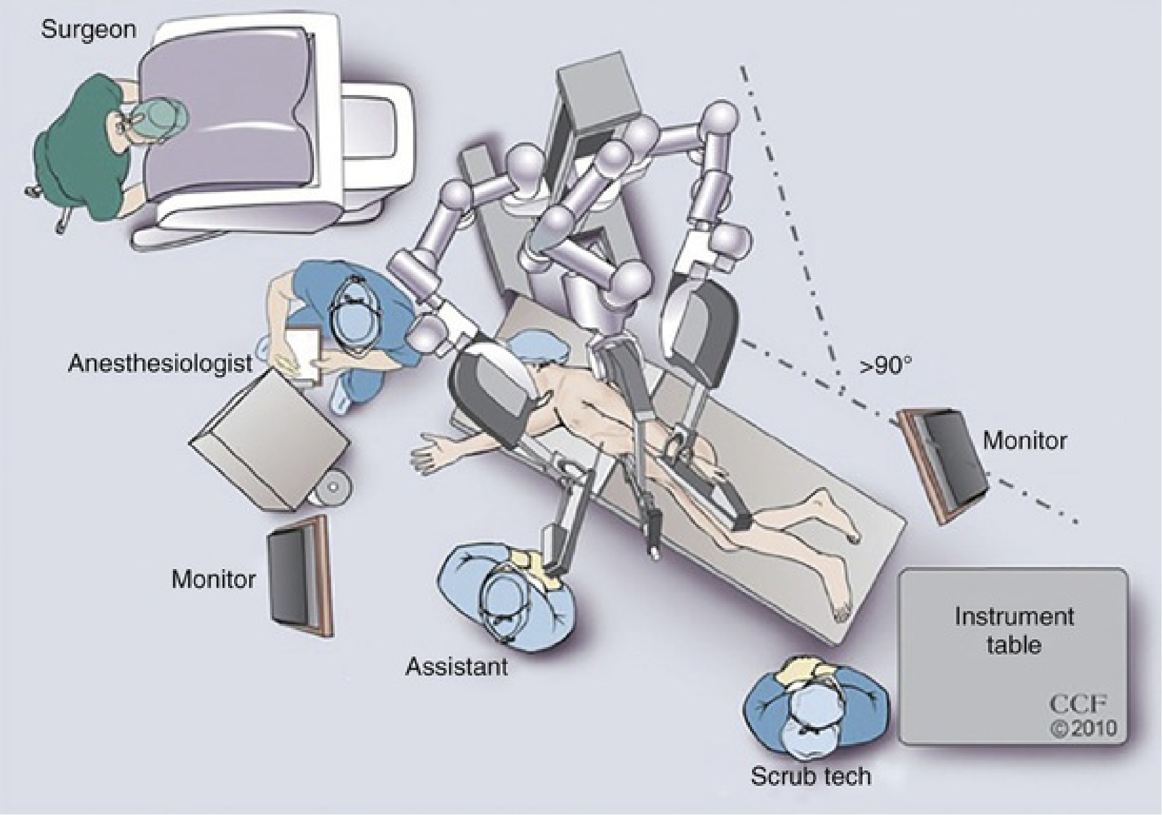
To provide more comfortable positioning of the surgeon's arms, a 6- × 4-foot, 6-inch platform can be used when the operating table cannot be lowered sufficiently to allow the surgeon to hold the laparoscopic instruments with his or her elbows held comfortably at the side rather than extended laterally. This configuration is helpful during suturing because it allows for more natural ergonomics.

Robotic.

For transperitoneal robotic-assisted laparoscopic renal and adrenal surgical procedures, the patient is again positioned in a modified lateral decubitus position. The assistant usually stands in front of the abdomen with the patient in the lateral decubitus position (i.e., for a left nephrectomy the assistant stands on the right side of the operating table). The robotic arms (i.e., patient-side cart) are brought in from the opposite side (i.e., facing the back with the patient in the lateral decubitus position) so that the robotic arms stretch over the patient and can then be docked to the preplaced ports. In general, it is best to angle the robot slightly so that the camera is pointing directly toward the site of interest. Accordingly, depending on the exact port placement, the robotic arms may be brought in at an angle toward the head of the patient, as opposed to perpendicular to the operating table, to minimize clashing of the robotic arms once docked (eFig. 14.5). The instrument table and the scrub nurse are best located at the foot of the bed on the same side of the patient as the surgical assistant so that instruments can be easily handed to the surgical assistant (see Fig. 14.4B). The robotic console can be placed anywhere in the room remote from the operating table and instrument table so that it is out of the way but in view of the patient and anesthetic monitors. All incoming lines from insufflators, suction and irrigation, and electrosurgical devices enter either from the contralateral foot side of the table or the ipsilateral head of the table.



EFIG. 14.5 Angulated placement of the robotic tower to minimize clashing of the robotic arms during transperitoneal (i.e., renal and adrenal) upper abdominal procedures.

Retroperitoneal Procedures in the Upper Abdomen

Laparoscopic.

For retroperitoneal renal and adrenal procedures, the patient is placed in the true 90-degree lateral decubitus position with the body at a right angle to the table. All of the proper steps for padding in this position should be followed (see previously). **The table is angled at the hip to accentuate and increase the distance between the 12th rib and the iliac crest. Maximizing this distance is paramount with regard to port placement.** The primary surgeon and the camera assistant stand facing the patient's back (Fig. 14.6A). The scrub nurse or technician stands facing the patient's front, and instruments are handed across the patient accordingly.

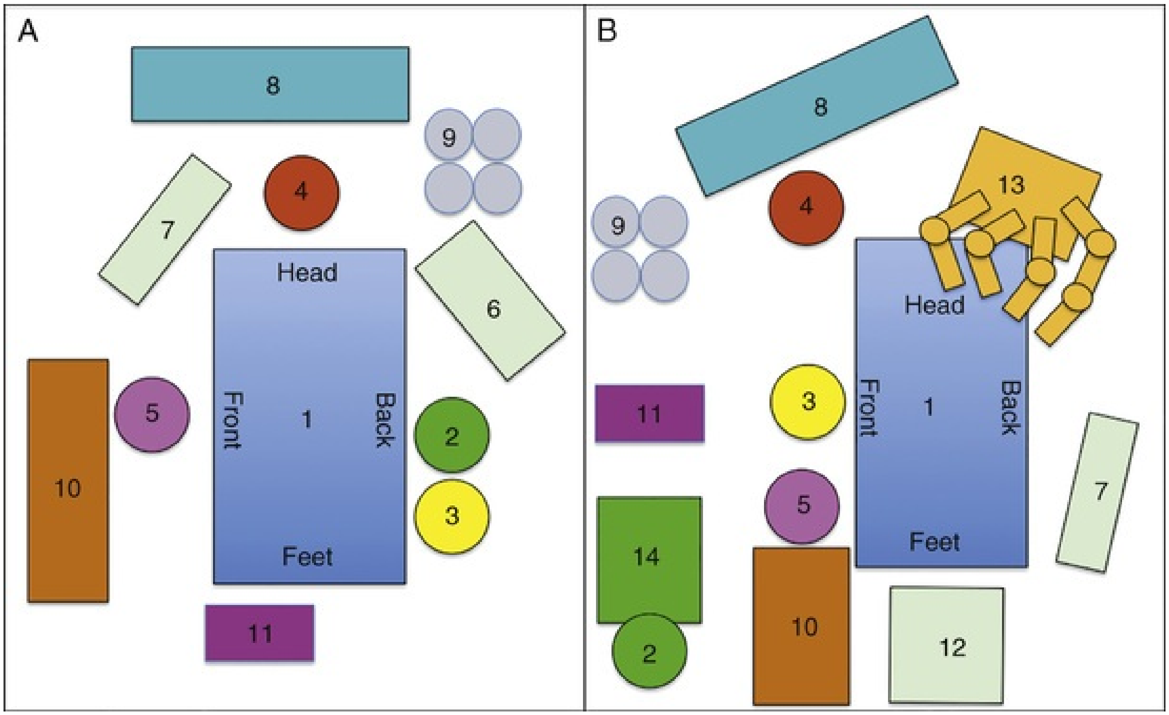


FIG. 14.6 Placement of the operative team for retroperitoneal procedures in the upper abdomen. (A) Laparoscopic procedure. (B) Robotic procedure. *1,* Operating table; *2,* surgeon; *3,* assistant; *4,* anesthesiologist; *5,* scrub assistant; *6,* laparoscopic cart or tower; *7,* auxiliary video monitor; *8,* anesthesia equipment; *9,* suction and irrigation unit; *10,* scrub assistant's instrument table; *11,* electrocautery unit; *12,* ancillary vision cart; *13,* robotic tower; *14,* surgeon's console.

Robotic.

For retroperitoneal robotic-assisted renal and adrenal procedures, the patient is similarly placed in the true 90-degree lateral decubitus position. The surgical assistant can stand facing either the patient's abdomen or his or her back depending on the surgeon's preference for port placement. The instrument table and scrub nurse are best placed on the same side as the assistant near the foot of the table. The robotic arms are brought in over the head of the patient (Fig. 14.6B). Because the robotic arms are positioned over the patient's head, the anesthesiologist and the anesthetic cart and monitors should be positioned off to the side, in front of the patient, at the head of the bed.

Transperitoneal and Extraperitoneal Pelvic Procedures

Laparoscopic.

The patient is positioned in the supine position with the legs on split-leg positioners or elevated in stirrups that have knee and leg supports to avoid perineal nerve injury. The table is angled (flexed) slightly at the hip to accentuate the pelvis. The patient's arms are tucked at the sides; plastic sleds can be used to support the arms. A slightly snug chest strap should be placed directly across the patient's chest. The table is placed in the 30-degree Trendelenburg position. The surgeon stands on the side of the table where he or she is comfortable, and the assistant stands on the opposite side (Fig. 14.7A).

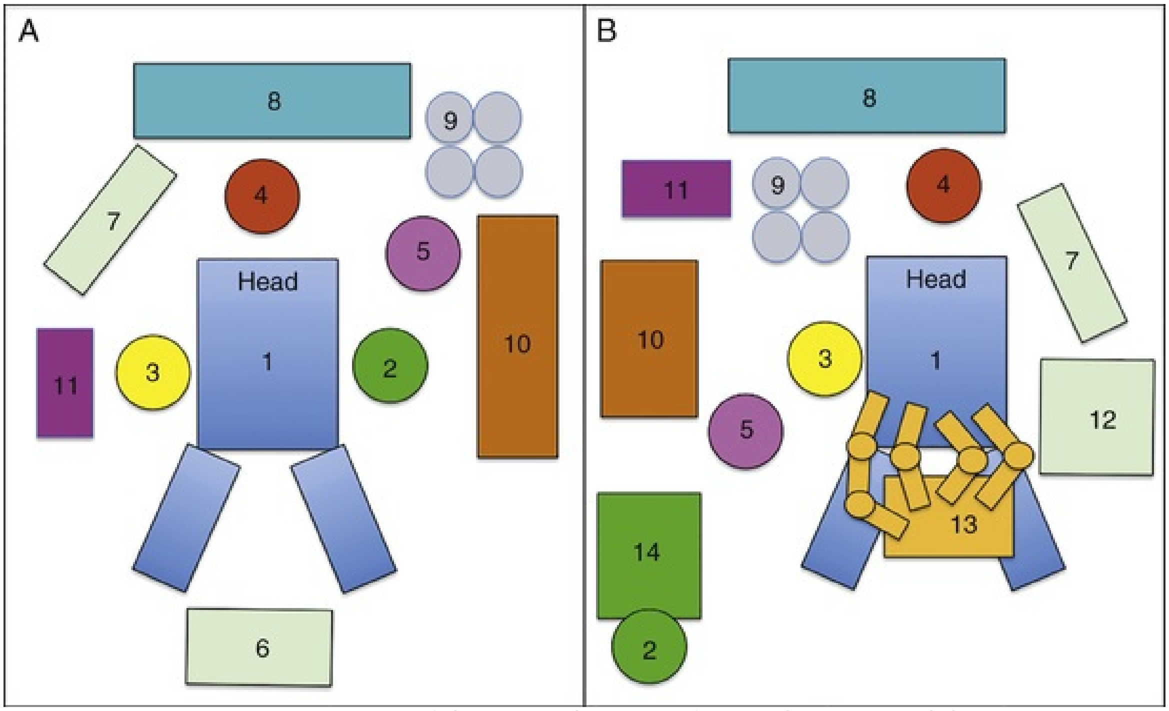

FIG. 14.7 Placement of the operative team for pelvic surgery. (A) Laparoscopic procedure. (B) Robotic procedure. *1,* Operating table; *2,* surgeon; *3,* assistant; *4,* anesthesiologist; *5,* scrub assistant; *6,* laparoscopic cart or tower; *7,* auxiliary video monitor; *8,* anesthesia equipment; *9,* suction and irrigation unit; *10,* scrub assistant's instrument table; *11,* electrocautery unit; *12,* ancillary vision cart; *13,* robotic tower; *14,* surgeon's console.

Robotic.

For robotic procedures on the pelvis the patient is positioned exactly as described previously for laparoscopic pelvic procedures when using the da Vinci S or SI systems. After port placement, the robot is positioned between the patient's legs, and the assistant can remain on either side of the table depending on surgeon preference (Fig. 14.7B). The scrub nurse or technician can be positioned on the same side as the assistant to facilitate passing instruments because passing instruments across the robotic arms can be cumbersome. A benefit of using the da Vinci Xi system is that the robot can be positioned on either side of the table as the mobile boom-mounted system can be configured for pelvic cases and that it eliminates the need to place the patient in stirrups.

Performing the Procedure

Before the Initial Incision

A checklist ensuring that all essential equipment is present and operational should be completed just before initiation of the pneumoperitoneum (see Box 14.1).

Additional items to check when using the da Vinci Robotic System include ensuring that all plugs for the console, vision cart, and patient-side cart are plugged into different circuits and that all cables connecting these carts are connected properly. The system should be turned on, and the self-test and homing routine should be complete. The three-dimensional (3D) camera and endoscopes should be calibrated, the image black and white balanced, and target alignment performed according to the manufacturer's instructions. The patient-side cart should be draped and ready.

Achieving Transperitoneal Access and Establishing the Pneumoperitoneum

Achieving transperitoneal access is the first step before establishing a pneumoperitoneum. This can be done using either a closed (i.e., Veress needle) or open (i.e., Hasson cannula) technique.

Closed Techniques

Veress Needle.

A disposable (70- or 120-mm, 14-gauge, and 2-mm outer diameter) or nondisposable Veress needle can be used. Proper needle function should be ensured before the procedure. Specifically, the blunt tip of the needle is tested to make sure the spring retracts easily and the needle is connected to the CO_2 line to ensure that there is no resistance to gas inflow (i.e., at 2-L/min flow, pressure remains at ≤2 mm). Last, saline is flushed through the needle with the tip manually occluded to make sure there is no leakage at the juncture between the shaft and the hub of the needle.

For proper placement the Veress needle is grasped at midshaft and is passed perpendicularly through skin using a gentle, steady pressure. Two points of resistance are traversed: the abdominal wall fascia and the peritoneum.

Sites for Needle Passage.

With the patient in the supine position, the head of the bed is lowered 10 to 20 degrees; insertion of the Veress needle is commonly accomplished at the superior border of the umbilicus. There are certain advantages to choosing the umbilical area as the site for initial trocar placement: the abdominal wall is thinnest, and postoperative cosmesis is excellent. However, this point of entry is fraught with the potential for injury to a major vessel, in particular the left common iliac vessels, aorta, or vena cava. In consideration of the umbilical area as the site for Veress needle placement, body habitus influences the relative location of the umbilicus to underlying vascular structures. In obese patients, the umbilicus tends to migrate inferiorly, whereas in nonobese patients the umbilicus lies in its commonly described position, directly above the bifurcation of the aorta and vena cava. Thus, for umbilical access in nonobese patients, the Veress needle should be passed through the abdominal wall angled toward the pelvis to avoid injury to the bowel and great vessels that lie directly beneath. In more obese patients, because the umbilicus lies more caudad, less angulation is needed and the Veress needle should be passed perpendicular to the umbilical incision (Loffer and Pent, 1976).

The right or left lower quadrant can also be used with the patient in the supine position, decreasing the likelihood of vascular injury. However, surgeons must be cognizant of risk for colonic injury with this site. If the patient is in a lateral decubitus position, then the Veress needle can be passed two fingerbreadths medial and two fingerbreadths superior to the anterior superior iliac spine.

Other potential insertion sites when the patient is either supine or in a lateral decubitus position are at the Palmer point (i.e., subcostal in the midclavicular line on the left side) and at the corresponding site on the right side. The Palmer point is the preferred site when extensive intra-abdominal adhesions are suspected (Palmer, 1974). With either of these insertion sites care must be exercised; if the needle is inserted too deeply, there is the potential to hit the liver on either side or, rarely, the spleen on the left side. Alternatively, in the abdomen that has previously been operated on, insertion should be performed in an unscarred quadrant of the abdomen. If there is no scar-free area, then an open technique (see following) should be used.

The safety of the Veress needle technique has been demonstrated in numerous studies, including a study by Chung et al. (2003) that examined the outcome of 622 consecutive cases with Veress needle insertion. Prior abdominal surgery had been performed in 192 patients (31%), and the BMI was 30 or greater in 98 patients. Blind Veress needle placement was successful in 579 (93%), and outcome was not associated with laterality, type of surgery, or prior surgery. In 34 cases (5%), a minor laceration to the liver was managed conservatively without sequelae; and in 21 cases (3%), the omentum or falciform ligament was traversed without significant injury. No major complications, such as vascular or hollow-organ perforation, were caused by either the Veress needle or trocar.

Assessment of Proper Needle Placement.

First the aspiration-irrigation-aspiration test is performed. With the use of a 10-mL syringe containing 5 mL of saline, the Veress needle is aspirated to check for blood or bowel contents. Blood is easily discerned by the color, but bowel contents often appear as just small particulate matter and do require close attention on the part of the surgeon to discern. If this test result is negative, then the saline is injected into the abdominal cavity; this should occur without any resistance. Next, the plunger of the syringe is again withdrawn; no fluid should return into the barrel of the syringe. An additional injection of 2 to 3 mL of saline helps to expel any omentum that may have been sucked into the needle tip with the original aspiration technique. Last, the syringe is detached from the Veress needle and any fluid left in the hub of the needle should fall swiftly into the peritoneal cavity (i.e., **the "drop" test**).

Second, the advancement test can be performed. If the needle has truly just entered the peritoneal cavity, then the surgeon ought to be able to advance the needle 1 cm deeper without the tip meeting any resistance. Resistance at this stage usually means the needle is still in the preperitoneal space and must be advanced through the remaining peritoneum.

Insufflation should never be initiated unless *all* the signs for proper peritoneal entry (negative aspiration, easy irrigation of saline, negative aspiration of saline, positive drop test, and normal advancement test) have been confirmed. Once proper needle placement is verified, insufflation is started up to a maximal capacity of 9 L/min with the abdominal pressure set at 15 mm Hg. Free flow of CO_2 is confirmed if intra-abdominal pressure remains below 10 mm Hg, and free flow of CO_2 stops as soon as the preset limit of 15 mm Hg of intra-abdominal pressure is reached.

Stabilization of the abdominal wall fascia with towel clips or Allis clamps at the time of Veress needle puncture may help in stabilizing the fascia; however, the surgeon should not lift up on the fascia because this will only increase the space between the fascia and the peritoneum and will not change the intra-abdominal space.

Open Access Techniques

Hasson Technique.

The pneumoperitoneum can be more easily, and in a surgeon's early experience, more safely established using the open Hasson technique; however, its use involves making a larger incision and increases the chances of port-site gas leakage during the procedure. **The open technique is recommended specifically when extensive adhesions are anticipated. Studies have shown the open technique to be as efficient as the closed approach and may be safer in patients with prior abdominal surgery** (Bonjer et al., 1997).

In the unscarred abdomen, with the patient in the supine position, a 2-cm semicircular incision is made at the lower edge or slightly below the umbilicus. The fascia and peritoneum are opened individually with a transverse incision, sufficient to accommodate the surgeon's index finger. After visual and digital confirmation of entry into the peritoneal cavity, two 0 silk traction sutures are placed on either edge of the fascia. Next, the Hasson cannula is advanced through the incision with the blunt tip protruding (Fig. 14.8). The funnel-shaped adapter of the Hasson cannula is advanced until it rests firmly in the incision, and it is then tightened onto the cannula with the attached screw; fixation to the abdominal wall is provided with the fascial sutures that are wrapped around the struts on the funnel-shaped adapter of the Hasson cannula, thereby anchoring it in place. After removal of the obturator, free flow of CO_2 into the peritoneal cavity is achieved by attaching the CO_2 tubing to the cannula. The insufflator can be set at maximum inflow, thereby creating the pneumoperitoneum quickly.

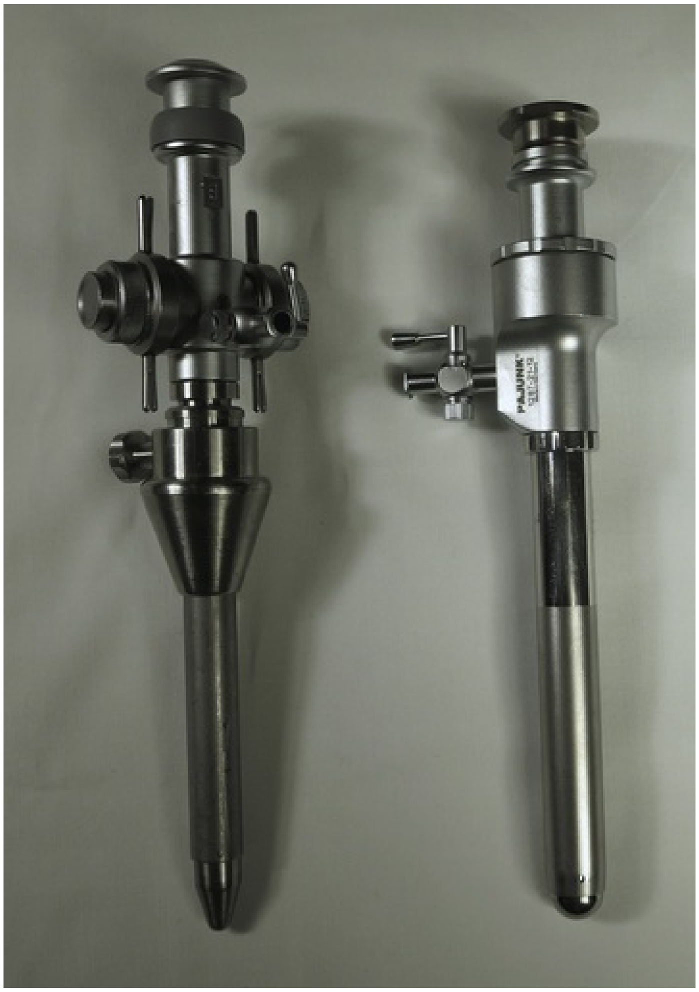

FIG. 14.8 Various reusable Hasson-type trocars.

Hand Port Access.

The pneumoperitoneum can be obtained before or after making the hand port incision. If the surgeon has little experience with achieving a pneumoperitoneum, the safest maneuver is to use an open technique and place the hand port into a 6.5- to 7.5-cm open incision and then create the pneumoperitoneum through the hand port (i.e., hand port access). For this technique, the procedure begins with making a standard midline or lower quadrant incision at the planned hand-assist site. The peritoneal cavity is entered in the standard open surgical fashion, after which the hand-assist device is placed according to the manufacturer's instructions. Next, a blunt cannula is passed through the hand-assist device and a pneumoperitoneum is established. Additional 5-mm or 10- to 12-mm ports can be placed rapidly under manual control with the surgeon's intra-abdominal hand being used to guide the additional trocars through the abdominal wall. Alternatively, a laparoscope can be placed through the port placed in the hand-assist device for insufflation, and the rest of the trocars can then be placed under direct vision.

Laparoendoscopic Single-Site Surgery

Advances in abdominal access technology combined with the development of curved and articulating laparoscopic instrumentation have made it possible to perform selected procedures through a single incision (typically a 2.5-cm transumbilical incision); using three access ports through this incision, the laparoscope and two working instruments can be introduced.

Much the same as for hand port access, the incision can be made before or after obtaining a pneumoperitoneum depending on surgeon preference. Typically, the incision is made periumbilically for cosmetic purposes. **The size of the skin incision should correspond to the surgical task at hand. If the procedure does not require removal of a large intact specimen, then the incision should be minimized to as little as 2.5 cm. If the procedure requires large intact specimen removal (as in donor nephrectomy), then the incision should be large enough to extract the specimen.** Once the incision has been made, several ports side by side or a single triport access device (see the following) can be placed and a pneumoperitoneum is reestablished at high flow.

After the first reports of laparoendoscopic single-site surgery (LESS) nephrectomy (Raman et al., 2007; Rane and Rao, 2008), this technique was refined for use across a broad spectrum of benign and urologic oncology procedures. **The theoretical advantages of LESS over standard multi-incision laparoscopy are improved cosmesis, decreased pain, and faster recovery time** (Merseburger et al., 2013; Raman et al., 2008). However, enthusiasm for this technique has precipitously declined because it is associated with a steep learning curve biased toward skilled laparoscopic surgeons (Sorokin et al., 2017). When surgeons approach LESS, the transition from standard laparoscopy to LESS should occur in a stepwise fashion by gradually decreasing the number of ports used until the procedure can be performed through a single incision. **Conversely, with difficulty performing a procedure using LESS, the surgeon should not hesitate to place one or more extra trocars at separate incision sites to improve triangulation and thereby ensure safety and a high-quality result.**

Robotic Laparoendoscopic Single-Site Surgery

Robotic laparoendoscopic single-site surgery (R-LESS) addressed numerous issues associated with LESS with significant enhancement in optics and ergonomics (Kaouk et al., 2009). At present R-LESS has been used for nephrectomy (partial, simple, and radical), pyeloplasty, nephroureterectomy, prostatectomy, and sacrocolpopexy. The recent development of a single-port (SP) robotic platform has allowed for continued evolution and advancement of this technique, and there is promise in the extraperitoneal and perineal approaches. A next-generation single-port robotic platform developed by Intuitive (SP1098) to be used for the Si and Xi systems is promising and allows for intercorporal triangulation while eliminating instrument clashing as seen with prior methods. Further studies are needed to better define its role in minimally invasive surgery.

Retroperitoneal Access and the Retroperitoneal Space

Technique for Balloon or Self-Styled Dilator Placement: Open (Hasson) Technique

The Hasson technique is the most commonly used technique because it affords the greatest precision during development of the retroperitoneal space (Gill, 1998). Initial access is obtained through a 2.0- to 2.5-cm transverse incision in the midaxillary line, just below the tip of 12th rib. The wound is opened with a pair of S-retractors. Under direct vision, the posterior layer of the lumbodorsal fascia is incised and muscle fibers are split or divided. The retroperitoneal space is entered **under direct vision** by making a small incision in the anterior thoracolumbar fascia with an electrocautery blade or, less commonly, by bluntly piercing the fascia digitally or with a hemostat. This fascial opening must be snug around the index finger and no larger so that intraoperative air leak is minimized. Index finger palpation of the belly of the psoas muscle posteriorly and the Gerota fascia–covered inferior pole of the kidney anteriorly confirms proper entry into the retroperitoneal space (Fig. 14.9A). The index finger is used to digitally create a space in this precise location for placement of the balloon dilator; two inflations of the balloon are then done—one directed cephalad and the second directed caudad to fully dilate the retroperitoneal space (Fig. 14.9B). Thus balloon dilation is performed anterior to the psoas muscle and fascia and outside and posterior to the Gerota fascia. In cases involving definitive ureteric mobilization (e.g., retroperitoneoscopic donor nephrectomy, nephroureterectomy), additional balloon dilation may be performed more caudad to the primary site of dilation (Gill et al., 1995). Similarly, during a retroperitoneoscopic adrenalectomy, it is helpful after the initial balloon dilation to move the balloon up higher in the retroperitoneum and perform a second, even more cephalic balloon dilation along the undersurface of the diaphragm (Sung and Gill, 2000).

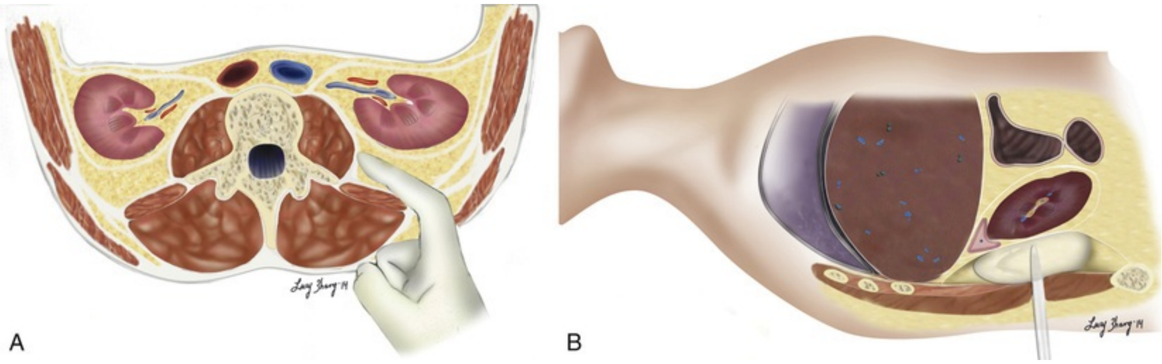

FIG. 14.9 (A) Access into the right retroperitoneum. Through the primary port incision at the tip of the lowest (12th) rib, open access is gained into the retroperitoneum after piercing the thoracolumbar fascia. Finger dissection is performed anterior to the psoas muscle and fascia to create a space for insertion of the balloon dilator. Confirmation that the finger dissection is indeed being performed in the proper plane is obtained by palpating the psoas and erector spinae muscles between the retroperitoneally located index finger and the fingertips of the opposite hand positioned on the patient's back. The fat-covered lower pole of the kidney can be palpated in a cephalad direction by turning the finger clockwise in the retroperitoneum on the right side. (B) Balloon dilation in the posterior pararenal space facilitates the creation of a working space for retroperitoneal laparoscopic nephrectomy *(coronal view).*

Balloon Dilation.

Gradual distention of a balloon dilator in the retroperitoneal space atraumatically displaces the mobile fat and moves the peritoneum forward relative to the immobile body musculature. This device thus creates a working space equivalent to the size of the balloon. Either commercially available balloon dilators or a self-styled dilator can be used.

Commercially Available Balloons.

Commercially available trocar-mounted preperitoneal balloon dissectors (PBDs) (e.g., Medtronic, Minneapolis, MN) are typically a transparent, high–tensile strength silicone balloon that is inflated with a sphygmomanometer bulb insufflator using room air (Fig. 14.10). The balloon has a maximum capacity of 800 mL (40 pumps of the inflating bulb). A primary advantage of commercially available balloons is that the balloon is affixed to the end of a stiff, hollow, transparent plastic shaft. This shaft allows precisely directed placement of the balloon dilator. Furthermore, because the laparoscope can actually be inserted into the shaft of the balloon dilator during the inflation process, it provides the capability for endoscopic confirmation of the proper positioning of the transparent balloon and of the adequacy of the controlled radial dilation of the extraperitoneal area. Balloon dilators are commercially available in two different shapes: a round balloon for dilation of the pelvic extraperitoneal space and a horizontally oriented, oblong balloon for dilation of the retroperitoneal space.

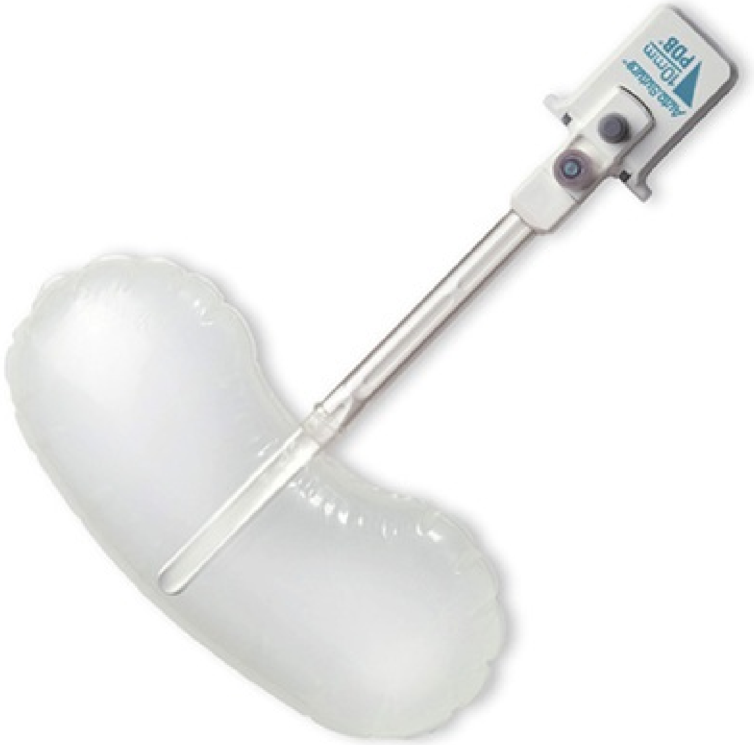

FIG. 14.10 Example of a commercially available balloon dilator for creating space in the retroperitoneum: preperitoneal balloon dissector. (Courtesy Medtronic, Minneapolis, MN.)

Self-Styled Dilators.

Gaur's original (Gaur, 1992) version of the balloon dilator was a size 7 surgeon's glove mounted on a No. 8 red rubber catheter. The external end of the catheter was connected to a sphygmomanometer bulb insufflator, and the balloon was insufflated to 110 mm Hg. After this initial description, several other self-styled dilators were described: the middle finger of a size 7 to 8 glove, two fingers of a size 7 to 8 glove tied over each other for additional strength, a sterile condom, and the cot of an O'Connor-style drape mounted on a 16- or 18-Fr red rubber or whistle-tip catheter (Chiu et al., 1995; Webb et al., 1993). For the balloons made from the middle finger of a surgeon's glove, the finger is affixed to the rubber catheter with two 0 silk sutures. These self-styled dilators were filled with saline rather than air. The device may be back-loaded into a well-lubricated (i.e., K-Y Jelly) 30-Fr Amplatz sheath to facilitate introduction through a laparoscopic port. Although it is economically advantageous, drawbacks of the self-styled balloon include the lack of a stiff shaft to manually direct the balloon into a specific location for precise dilation and the inability to endoscopically monitor the dilation process from within the balloon. In addition, the latex balloon has a tendency to rupture into multiple pieces, whereas the Silastic balloon usually leaves only one large fragment, making retrieval an easier task.

Complications associated with balloon dilation stem from improper balloon placement or balloon rupture. Intramuscular dilation may result in hernia formation, or inadvertent peritoneal disruptions may occur (Adams et al., 1996; Gaur, 1992).

Manual Dilation.

Creation of a working space within the retroperitoneum may also be achieved exclusively with a combination of digital and laparoscopic instrument dissection (Kerbl et al., 1993). After access to the extraperitoneal area is gained, to-and-fro movements of the laparoscope are performed to create a working space (McKernan, 1995). This technique has been used to perform various simple and advanced procedures in the retroperitoneum (Abbou et al., 1999; Rassweiler et al., 1998a). Although it is effective, potential disadvantages of this technique include frequent cleaning of the laparoscope and the lack of clear landmarks initially as a result of the smaller, undeveloped working space.

Extraperitoneal Access and the Extraperitoneal

Space

Technique for Balloon or Self-Styled Dilator Placement: Open (Hasson) Technique

A 1.5- to 2-cm curvilinear incision is made along the inferior umbilical crease. The anterior rectus sheath is incised vertically for 1.5 cm, and the rectus muscle is separated in the midline to expose the posterior rectus sheath. With the surgeon's index finger positioned posterior to the rectus muscle and anterior to the posterior rectus sheath, gentle tunneling motions are made in a caudal direction until the area of the symphysis pubis is reached. At this distal location, the fascia transversalis is punctured with the fingertip, and gentle side-to-side digital dissection is performed in the prevesical space, posterior to the pubic bone. Into this predeveloped space, a balloon dilator or self-styled dilator (see previous) is inserted and distended to create an adequate working space. Balloon dilation or self-styled dilation effectively displaces the prevesical fat and reflects the peritoneum cephalad. The balloon is initially inflated in the midline and then reinflated on either side to further expand the working area (Meraney and Gill, 2001).

Caveat: In earlier studies of retroperitoneoscopy, excessive subcutaneous emphysema and higher carbon dioxide levels were the norm because of the use of the standard Hasson cannula (Ng et al., 1999; Wolf et al., 1995); this situation was rectified with the introduction of the open access blunt balloon port, which has a balloon to secure it against the underside of the abdominal wall and a soft foam cuff to secure it to the outer abdominal wall, creating an airtight seal (Ng et al., 1999).

Limitations and Advantages of Transperitoneal Versus Extraperitoneal Approach to the Flank and Pelvis

Transperitoneal Versus Retroperitoneal Renal and Adrenal Surgery.

The transperitoneal and retroperitoneal approaches to the upper abdomen offer advantages and disadvantages. Retroperitoneoscopy is associated with unique anatomic orientation with limited anatomic landmarks, except for the psoas muscle. In comparison, the transperitoneal approach offers a very familiar anatomic approach with a number of landmarks (e.g., liver, spleen, large bowel). Retroperitoneal laparoscopy is also associated with a relatively restricted working space compared with transperitoneal laparoscopy. This results in a steeper learning curve with the retroperitoneal approach. Moreover, the fact that a comparatively limited space is available necessitates precise accuracy regarding the strategic placement of ports.

The degree of technical difficulty of the retroperitoneal approach increases in the presence of large specimens, including entrapment of these larger specimens, which may be very difficult. The latter problem of entrapment can be overcome by laparoscopically creating an intentional peritoneotomy at the end of the procedure to allow entrapment of the specimen within the larger peritoneal cavity.

Laparoscopic reconstruction and intracorporeal suturing are technically demanding procedures regardless of the approach. However, in the retroperitoneal space, reconstruction can be more challenging compared with transperitoneal laparoscopy because of suboptimal instrument angulation and a smaller working space. One potential way to overcome some of these limitations is to use a robotic approach to the retroperitoneum (Kaouk et al., 2008c).

Offsetting the limitations of retroperitoneoscopy are some distinct advantages. First, the risks of inadvertent bowel injury and postoperative ileus are minimized, although not eliminated (Kavoussi et al., 1993). This results in a slightly more rapid postoperative recovery compared with the transperitoneal approach. During retroperitoneoscopy and extraperitoneoscopy the bowel can be effectively and safely retracted within its peritoneal cover. Although out of sight, the bowel should never be out of mind, because bowel injuries can still occur.

Transperitoneal laparoscopy may be associated with an increased incidence of postoperative shoulder-tip pain, a feature rarely associated with retroperitoneoscopy. In addition, **extraperitoneoscopy and retroperitoneoscopy are associated with a significantly lower incidence of postoperative trocar site hernias.**

Another significant benefit of the retroperitoneal approach is the rapid and direct access to the renal hilum; the renal artery is the first hilar structure encountered and controlled. Furthermore, **if a partial nephrectomy is planned, it may be more effective to approach a posterior tumor from the retroperitoneal approach, whereas anterior tumors are often more easily approached from the transperitoneal approach**.

Contrary to common conception, the occurrence of an inadvertent peritoneotomy during retroperitoneoscopy does not usually interfere with the subsequent steps of the procedure, and conversion to a transperitoneal laparoscopic technique is not mandatory (Gill et al., 2000).

Although a retroperitoneal approach may not be advantageous for every surgery, there are certain instances in which this approach may be more appropriate, as in the case of multiple prior transabdominal surgeries. Conversely, a history of prior retroperitoneal surgery increases the difficulty of re-entering the retroperitoneal space and therefore should be approached with caution. Subsequent attempts at extraperitoneoscopy or retroperitoneoscopy should be ventured only by individuals with considerable experience and comfort with this approach. In our experience, prior percutaneous renal procedures do not necessarily constitute a contraindication to subsequent retroperitoneoscopy, provided that entry is away from the area of the prior nephrostomy tube placement.

Transperitoneal Versus Extraperitoneal Pelvic Surgery.

As with the upper abdomen, the transperitoneal and extraperitoneal approaches to the pelvis offer distinct advantages and disadvantages. The transperitoneal approach to the pelvis offers easy access to all areas of the pelvic cavity once the space of Retzius, iliac and obturator fossa, or the rectovesical space has been entered directly through the peritoneum. The working space is maximized because the peritoneum does not limit camera or instrument motion. However, potential limitations associated with this approach as compared with the extraperitoneal approach include the possibility of causing mechanical or thermal injury to the bowel, the necessity to use more extreme Trendelenburg positioning or additional retraction of the bowel, and the possibility of prolonged ileus. Overall, in large prospective studies the only significant difference between the extraperitoneal and transperitoneal approaches is that the extraperitoneal approach is associated with shorter operative times (Erdogru et al., 2004; Madi et al., 2007; Ruiz et al., 2004).

One undeniable advantage of the extraperitoneal approach is that it avoids the necessity of lysis of adhesions in patients who have had prior abdominal surgery. In contrast, for patients who have had prior laparoscopic inguinal hernia repair, a transperitoneal approach is more advantageous.

Unlike with retroperitoneoscopy, the occurrence of a peritoneotomy during extraperitoneoscopy may interfere with the performance of subsequent extraperitoneal dissection, and conversion to a transperitoneal technique may be required (Meraney and Gill, 2001).

In summary, for most cases there does not seem to be a clear advantage to use of a transperitoneal versus extraperitoneal approach for laparoscopic and robotic pelvic surgery. In selected cases described earlier there may be advantages of one approach over the other.

Access Technology: Trocars, Hand Ports, and Single-Port Access

Trocars

Trocars enable the laparoscopist to introduce working instruments into the gas-filled abdomen or retroperitoneum. They also maintain the pneumoperitoneum by conveying the insufflant and may serve as pathways for delivering small amounts of dissected tissue from the surgical area. Typically a trocar consists of an outer hollow sheath (also called a *cannula* or *port*) and an inner obturator, which is removed as soon as the outer sheath has entered the peritoneal cavity.

A variety of nondisposable and disposable trocars are available (Fig. 14.11) with one-way valves and multiseal valves. Standard models range from 3 to 20 mm in diameter and 5 to 20 cm in length. One-way valves within the trocar allow the surgeon to exchange instruments through the port without the escape of significant amounts of gas. Multiseal-type valves accommodate the passage of 5-mm and larger instruments without any air leak occurring; if large amounts of tissue are to be withdrawn, removal of the outer seal or of the entire valve is necessary for this procedure. The outer seal and valve can then be replaced before reinsertion of instruments.

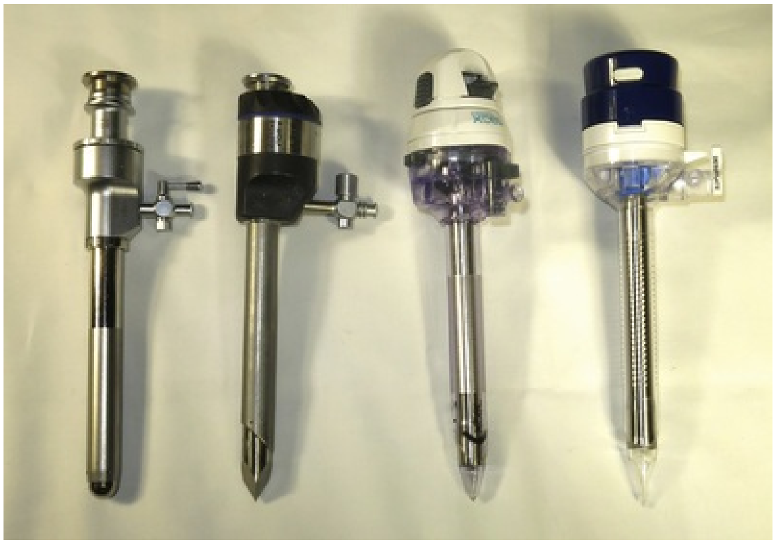

FIG. 14.11 Various trocar designs showing *(left to right)* reusable blunt-

tipped, reusable bladed, and two disposable visual obturator fascial dilating designs.

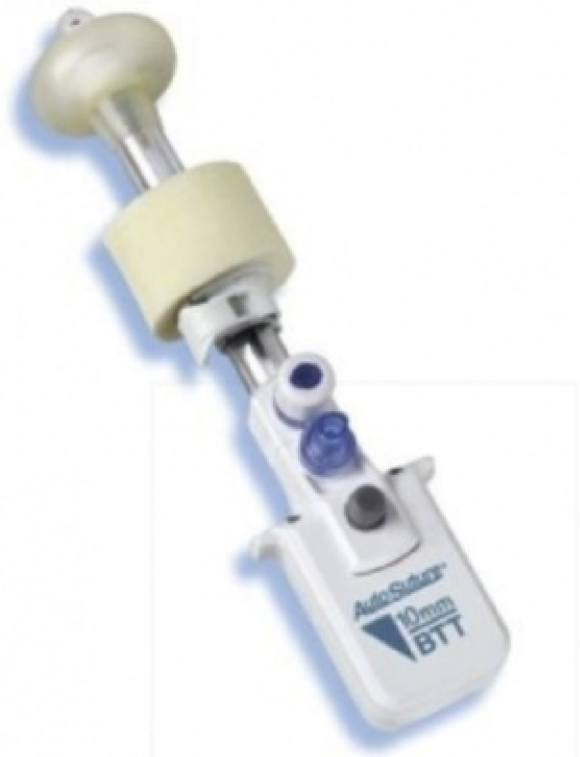
Initially, only “cutting,” sharp-tipped or bladed, trocars were available. On these trocars a blade on the obturator incised the various layers of tissue as it entered the peritoneal cavity. To protect the underlying viscera from the sharp tip of these trocars, a plastic safety shield was later incorporated into the disposable trocars that would spring forward to shield the blade once the trocar entered the gas-filled abdomen. **However, bladed trocars should be only of historical interest because they have been superseded by safer noncutting dilating trocars (i.e., blunt), which no longer require a safety shield.** These trocars enter the abdomen by spreading the abdominal wall musculature rather than cutting it. Therefore there is less chance of injuring an abdominal wall vessel, and the resulting entry site is less prone to subsequent herniation. Indeed, studies have shown the risk of inferior epigastric injury or port site herniation is fivefold less with blunt versus sharp trocars (Hashizume and Sugimachi, 1997; Thomas et al., 2003). In addition, a recent meta-analysis demonstrated a lower relative risk of trocar site bleeding (3% vs. 9%) and overall complications (3% vs. 10%) with blunt compared with bladed trocars (Antoniou et al., 2013).

Other blunt-tipped trocars are produced by all of the major trocar manufacturers. These devices have a variety of tips that enable their placement by spreading the tissues; some also have a clear plastic tip (i.e., optical trocar) so that the surgeon can pass an endoscope into the trocar to endoscopically monitor its passage through the abdominal wall and its entry into the gas-filled abdomen.

For the da Vinci Robotic System the trocar type that will accommodate the camera lens depends on whether the Si or Xi system is used. The Xi camera fits through any of the 8-mm trocars, whereas the Si camera requires a 12-mm trocar for use. The instruments fit through proprietary reusable 8-mm trocars that couple directly with the robotic arms. These reusable metal trocars have disposable valves that must be changed with each new case and the option of a reusable blunt inner cannula or a bladeless disposable inner cannula for use during placement.

In traditional flap-valve or trap door ports, a reducer is necessary to allow downsizing of working channels in 10-mm or larger trocars to accommodate smaller, 5-mm working instruments without any leakage of CO_2. However, the development of multiseal technology and the even newer AirSeal technology (CONMED, Utica, NY; discussed later) has resulted in valves that can accommodate 5- to 12-mm instruments without the need for a reducer, which can save significant time during a long procedure.

Retention of the cannula at the port site is essential to decrease air leak and subcutaneous emphysema and facilitate the timely completion of a procedure. In the past it was necessary to affix a suture to the insufflation side port and the skin to secure the trocar. At present, myriad retention mechanisms prevent dislocation of cannulae, such as threaded sleeves, adjustable threaded sleeves, expandable arms, and inflatable balloons. The Blunt Tip Trocar (Medtronic, Minneapolis, MN) (eFig. 14.12) has a retention balloon that can be inflated in the peritoneal cavity and then drawn up tightly against the peritoneal side of the abdominal wall; an outer foam or rubber sealing ring can then be advanced down the extra-abdominal shaft of the cannula, thereby sandwiching the abdominal wall between the inflated balloon and the foam or rubber seal, effectively precluding any leakage of gas during the case. **Use of this device minimizes CO_2 leakage around the primary port incision, thus reducing the incidence of subcutaneous emphysema and hypercarbia.** This is especially effective when doing retroperitoneoscopic procedures.



EFIG. 14.12 Blunt-tipped trocar with balloon tip.

A technologic advance in trocar and insufflation technology has addressed some of the limitations of existing trocar systems including air leak, need for reducers, and specimen removal. The AirSeal System (CONMED, Utica, NY) consists of a specialized Intelligent Flow System insufflator (eFig. 14.13A) featuring a circulatory flow design, a valve-free Access Port (eFig. 14.13B and C), and a Tri-Lumen filtered tube set (eFig. 14.13D). This system has the ability to provide a substantially more stable pneumoperitoneum (Bucur et al., 2016) despite continuous high-flow suction, trocar dislodgment, or excessive port-side leakage. The stable pneumoperitoneum allows for procedures to be routinely performed at lower insufflation pressures (i.e., 8–12 mm Hg) in the majority of cases. The valve-free design of the Access Port allows smudge-free scope insertion, intact specimen removal, and easy insertion and withdrawal of instruments of varying sizes. The AirSeal System also provides continuous smoke evacuation without the fear of venting surgical smoke and plume into the operating room.

Hand-Assist Devices

The most common hand-assist devices available are the GelPort (Applied Medical Resources, Rancho Santa Margarita, CA) and the Endopath Dextrus (Ethicon, Somerville, NJ) (Fig. 14.14). An important caveat with using hand-assist devices is the impact on the surgeon. Studies have shown that compared with standard laparoscopy, pain and numbness of the surgeon's hand, wrist, and forearm and, to a lesser extent, overall fatigue are much greater with use of a hand-assist device (Gofrit et al., 2008; Monga et al., 2004). Both devices maintain peritoneal gas pressure while allowing for insertion of the surgeon's hand or surgical instruments into the abdominal cavity.

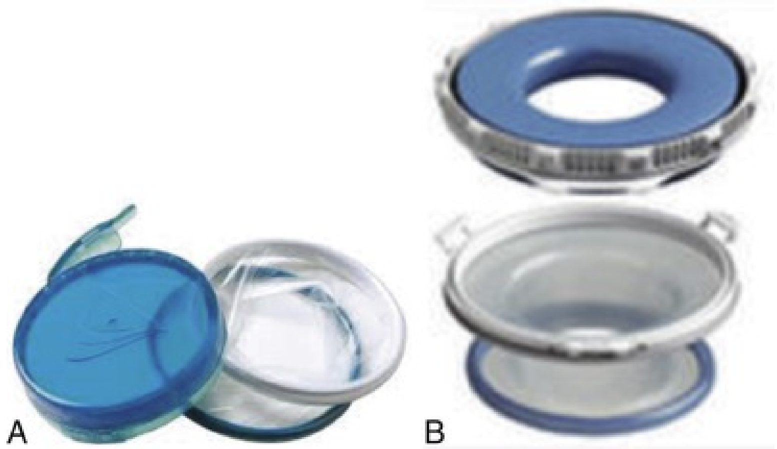

FIG. 14.14 Hand port devices. (A) GelPort. (Courtesy Applied Medical Resources, Rancho Santa Margarita, CA.) (B) Endopath Dextrus. (Courtesy Ethicon, Somerville, NJ.)

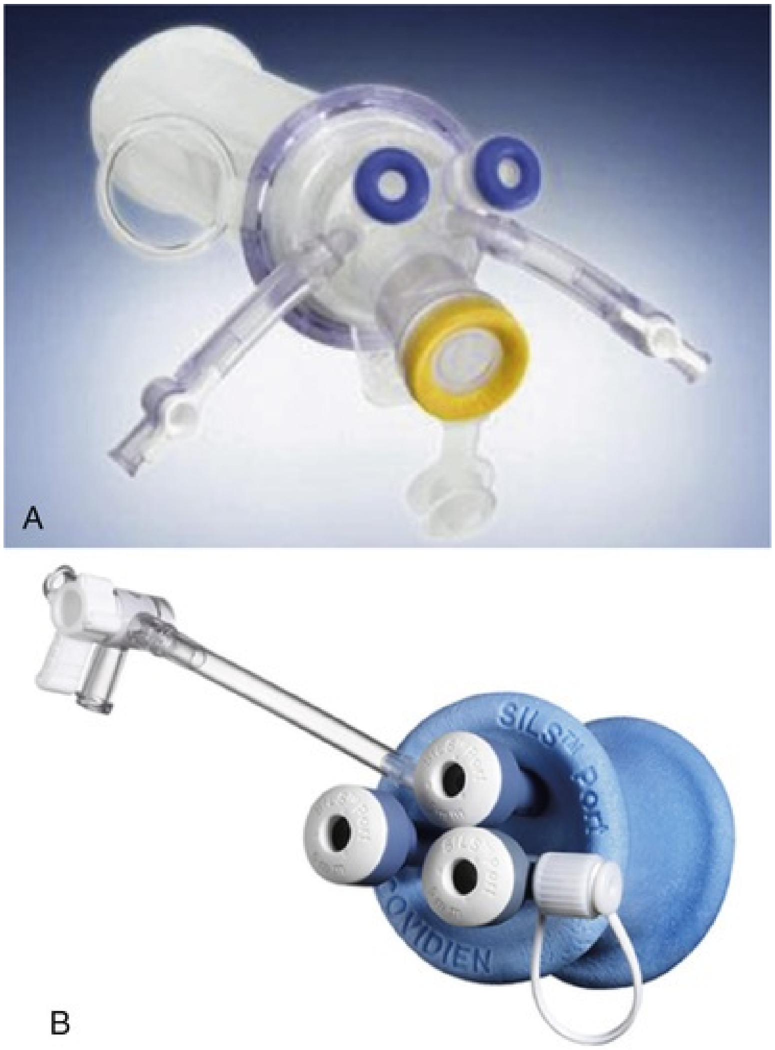
Laparoendoscopic Single-Site Surgery Access Devices

Two basic methods are used to perform LESS. One technique is to make a 2.5-cm incision, typically periumbilical or transumbilical (although an alternate site may be necessary), through which a skin flap can be raised off the abdominal wall fascia. Then, through this single incision, several (two to four) standard 5-mm laparoscopic ports can be placed in proximity to one another. A laparoscope and working instruments can then be placed through these ports. This is obviously the most cost-effective technique.

Alternatively, a commercially available single-site surgery device can be used. These devices currently require a single incision that is typically placed periumbilically or transumbilically unless the procedure dictates an alternate site. Currently the most popular devices that are available for commercial use are the TriPort15/TriPort+ (Olympus, Center Valley, PA) and the SILS Port (Medtronic, Minneapolis, MN).

The TriPort15 contains three instrument ports and two insufflation valves (eFig. 14.15A), whereas the TriPort+ contains four instrument ports and two insufflation valves. Both accommodate different sizes of laparoscopic instruments and feature duckbill/lipseal valves that allow for the introduction and removal of instruments while maintaining pneumoperitoneum. The same manufacturer also makes a five-port model called the QuadPort+ that contains five instrument ports and two insufflation valve sites and can be easily introduced through a 2.0-cm incision.



EFIG. 14.15 Commercially available ports for laparoendoscopic single-site surgery. (A) TriPort15. (B) SILS Port.

The third available device is the SILS Port, which can be placed into a 2-cm incision and can house three 5-mm ports or two 5-mm ports and a 5- to 10-mm port (eFig. 14.15B).

Robotic Laparoendoscopic Single-Site Surgery Devices.

Intuitive Surgical has developed a single-site platform for both the da Vinci Systems. The da Vinci single-site port system is a five-lumen port that provides access for two single-site instruments, the 8.5-mm endoscope, a 5- or 10-mm accessory port, and an insufflation adaptor (eFigs. 14.16A and B). The port has a pliable architecture that enables simple and safe entry into a 2.0- to 2.5-cm incision. Curved 5-mm instrument cannulae and trocars have been designed for specific use with the single-site port and are meant to optimize triangulation toward the target anatomy and provide an unobstructed view of the surgical field (eFig. 14.16C). More recently, a complete change in the platform for R-LESS has been developed to overcome the challenges of instrument clashes and improve triangulation of the arms. The novel da Vinci SP 1098 platform uses EndoWrist technology to avoid difficulties with instrument triangulation and is currently in the preclinical research phase.

Trocar Placement

Placement of Initial Trocar

When the Veress needle technique is used after establishment of the pneumoperitoneum, an incision is made for placement of the initial trocar. Alternatively, if an incision was made for placement of the Veress needle, the edges of the wound and subcutaneous tissue are spread with blunt forceps. Next, the trocar is held in the dominant hand with the middle finger extending along the shaft, and the trocar is inserted using a twisting downward motion. The nondominant hand can be placed at the level of the skin, gently holding the trocar to stabilize it and prevent a sudden advancement. If the surgical site is in the mid to upper abdomen, then the trocar is passed perpendicular to the umbilical incision; however, for pelvic procedures, the trocar is directed 70 degrees caudad. Proof of entering the gas-filled intraperitoneal cavity is the sound of CO_2 escaping from the open sidearm. After the sidearm is closed, the obturator is removed and the CO_2 insufflation line is connected to the side port of the trocar. Alternatively, if a clear blunt port (i.e., optical trocar) is used, a 0-degree laparoscopic lens is placed within the port so that the entire entry of the trocar is endoscopically monitored.

Some advocate for increasing the pneumoperitoneum after achieving access with the Veress needle in preparation for initial trocar placement to decrease the risk of underlying vascular or visceral injury with trocar insertion (Vilos et al., 2007). It is recommended to increase the pressure to 20 mm Hg. However, some data suggest this may not increase the volume of the pneumoperitoneum or ease of trocar insertion (McDougall et al., 1994).

When an **open technique** is performed to obtain the pneumoperitoneum, the Hasson-style cannula used to obtain access to the abdomen also serves as the initial trocar.

Hand-Assist Placement

The hand-assist device can be placed either as an initial “port,” described earlier, or as a secondary port depending on the surgeon's preference. When placed as a secondary port, a Veress or Hasson pneumoperitoneum is initially established and the hand-assist device is then placed under endoscopic monitoring. Establishing the pneumoperitoneum before hand port placement can help to minimize the size of skin incision for the hand port, as the skin is on stretch. The surgeon should carefully plan out the hand port entry site as well as the additional instrument and camera port sites. Every hand port device has a “footprint” that can be drawn on the abdominal wall; that footprint varies depending on the diameter of the external appliance. **Care should be taken to plan out the additional trocar sites carefully to avoid interference between the hand port and the instrument ports;** this is most easily done once the pneumoperitoneum has been established. After the footprint has been traced, the hand port incision site is marked; the length of the incision should correspond to the surgeon's glove size (e.g., 7 glove size = 7-cm incision). The skin is incised, and the fascia is divided. The peritoneum is entered, and the insufflation is temporarily stopped. The hand port device is then placed according to the manufacturer's instructions.

Before initiating a hand-assist procedure, the surgeon is advised to wrap the arm-glove seam on the hand that is to be used through the hand port either with a 1010 drape or an Ioban (3M, St. Paul, MN) “sticky drape” to waterproof his or her arm. **Last, the use of a brown glove on the intra-abdominal hand is recommended because it does not reflect the light from the laparoscope and thus reduces glare** (Wolf, 2005).

Secondary Trocar Placement

After obtaining access, the first step before secondary trocar placement is to inspect the entire abdomen systematically to rule out any injury to the underlying viscera that may have occurred during access or placement of the initial trocar. After this, the surgeon can proceed with secondary port placement.

Number, size, and exact location of secondary trocars depend largely on the intended laparoscopic procedure. Their configuration should be planned so that neither the tips nor handles of the cannulas cross or come into close contact with one another (a problem termed *crossing swords* and *rollover,* respectively) so that adequate working space is provided for all instruments to be used during a particular procedure and allowing for effective triangulation at the surgical site by the endoscope and two working ports. In general, it is reasonable to place the ports in a four-point diamond pattern so that the site of the operation is encircled within the diamond. **This is particularly important when considering reconstructive renal procedures, because the angle between the horizontal plane and the needle drivers should be less than 55 degrees, whereas the angle between the surgeon's suturing instruments should be in the 25- to 45-degree range** (Rassweiler and Frede, 2002).

It is also important to place each port so that it is pointing toward the surgical field to avoid continued forceful redirection of the port during the procedure that may result in widening of the tissue tract around the port and development of subcutaneous emphysema.

Standard Approach.

Secondary trocars are placed under direct optical control. The 30-degree lens is ideal for this portion of the procedure because turning the lens 180 degrees away from the surgical site provides the surgeon with a panoramic view of the anterior abdominal wall. The operative lights are dimmed, and the tip of the laparoscope is moved upward toward the intended site of port placement, thereby, in the thin patient, transilluminating any superficial blood vessels that must be avoided while passing the trocar. With a blade, a skin incision is made just wide enough to accept the selected cannula. When placing secondary ports, the surgeon should direct them toward the intended surgical field to provide tension-free maneuverability of the laparoscopic instruments. This is especially important in obese patients because the errant port will provide resistance to the surgeon throughout the rest of the procedure. Similar to placement of the initial port, all secondary ports are advanced through the abdominal wall using a slow, twisting motion and constant pressure. Each secondary port is passed into the peritoneal cavity under meticulous endoscopic monitoring. To prevent dislocation, ports that do not possess self-retaining mechanisms may be anchored to the skin using No. 2 nonabsorbable sutures. **In this regard, the laparoscopist should never use a metal trocar in conjunction with an outer plastic retaining ring because stray current can no longer be harmlessly dissipated through the metal cannula directly to the surrounding peritrocar abdominal wall. Therefore any juxtaposed visceral structure may be damaged in an area remote to the laparoscopist's vision.**

Hand-Assist Approach.

When the hand-assist device is in place, then secondary trocars can be placed with digital guidance. After inspection of the abdomen rules out any potentially interfering adhesions, the surgeon's index finger is placed on the underside of the abdominal wall at the planned site of trocar placement. A skin incision is made over the surgeon's index finger, and the nonbladed trocar is passed with the other hand and guided by the surgeon's finger into the abdominal cavity. This is a very rapid and safe way to place all of the secondary nonbladed trocars.

Trocar Configuration

A number of different trocar configurations exist for transperitoneal or retroperitoneal upper abdominal laparoscopy and robotics. Details and diagrams of these configurations can be found in Chapter 103. Similarly, a number of trocar configurations exist for transperitoneal and extraperitoneal laparoscopic and robotic pelvic procedures, which are detailed in Chapter 157. Most important, regardless of the configuration chosen, is to ensure meticulous placement of the ports to minimize instrument clashing intracorporeally and extracorporeally.

Robotic Considerations

If a robotic procedure is planned, then the camera port is either an 8-mm (Xi) or 12-mm (Si) trocar site depending on the da Vinci system used and the two (or three if the fourth arm is used) auxiliary ports are 8 mm. **All the ports must be placed 8 to 10 cm apart to reduce the possibility of the robotic arms clashing with each other.** In addition, if the patient is in a flank position, then the lowest port placement should not be inferior to the umbilicus or the arm may be blocked from a full range of motion by the patient's upside leg. An assistant's port is placed on a line either caudal or inferior to the robotic arms; placement of the assistant's port between the arms of the robot makes it awkward for the assistant to work and limits the range of motion of the assistant's instrument because of clashing with the arms of the robot. All 8-mm robotic ports must be advanced to ensure that the thick black marking on the shaft of the trocar is below the abdominal wall.

Laparoscopic Instrumentation

Instruments for Visualization

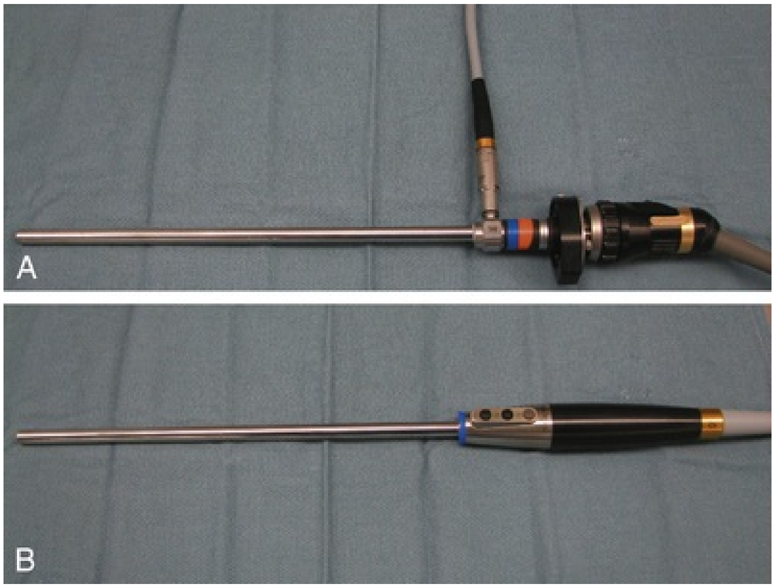
To create a laparoscopic image, four components are required: the laparoscope, light source, camera, and monitor. To record the image, video recorders, digital video discs, and video printers are available.

Laparoscope and Camera

Standard Systems.

The most commonly used laparoscopes have 0- or 30-degree lenses (range, 0 to 45 degrees) and are available in sizes from 2.7 to 10 mm. Typically, the 30-degree lens provides the surgeon with a more complete view of the surgical field than the 0-degree lens, allowing the surgeon to peer around vascular structures by rotating the lens. Deflectable laparoscopes have been developed in which the tip of the endoscope can deflect in four directions up to 100 degrees (EndoEYE Deflectable-Tip Video Laparoscope [Olympus, Center Valley, PA]), which offers many potential angles from which to view a structure but requires an adept assistant. Another endoscope design is the EndoCAMeleon (Karl Storz, Tuttlingen, Germany). This scope maintains the familiar feel of a standard rigid laparoscope but has a variable-view swing prism that enables the surgeon to change viewing angles from 0 to 120 degrees. An advantage of the EndoCAMeleon is that it has a standard eyepiece, allowing it to be used with most camera systems.

With standard laparoscopes, image transmission uses an objective lens, a rod-lens system with or without an eyepiece, and a fiberoptic cable. From the eyepiece, the optical image is magnified and transferred to the camera and onto the monitor. Light is transmitted from the light source through the fiberoptic cable onto the light post of the laparoscope (eFig. 14.17A). Some laparoscopes have a miniature charge-coupled device (CCD) camera mounted at the tip (EndoEYE [Olympus, Center Valley, PA]), which improves image quality and avoids the need for an external light cord that can sometimes impede the movement of other instruments (eFig. 14.17B).



EFIG. 14.17 (A) Standard rod and lens laparoscope and camera. (B) Laparoscope with a mini–charge-coupled device camera mounted at the tip.

The most vexing problem with any laparoscope is fogging of the lens. To prevent fogging of the laparoscope after insertion into the warm intraperitoneal cavity, the laparoscope should be warmed before passing it into the abdomen. Several methods for this include using a container holding warm saline or using a warming thermos (Applied Medical Resources). In addition, wiping the tip with a commercial defogging fluid or with povidone-iodine solution is also recommended. Alternatively, an all-in-one visualization system cleans and defogs the camera simultaneously (Medtronic, Minneapolis, MN). Should moisture buildup occur between the eyepiece and the camera, both components must be disconnected and carefully cleansed with a dry gauze pad; this is not a problem with the digital endoscopes because the only connection is from the endoscope directly into the display box. A final important note is to ensure that the sterile scope is white balanced.

The **camera system** consists of a camera and a video monitor. All currently made cameras can be gas or liquid sterilized, thereby facilitating their use and limiting possible intraoperative contamination. For standard laparoscopes the camera is attached directly to the end of the laparoscope and transfers the view of the surgical field through a cable to the camera box unit. After reconstruction of the optical information, the image is displayed on one or two video monitors.

Three-Dimensional Systems.

3D laparoscopic systems offer the surgeon the distinct advantage of depth perception. Optimal 3D laparoscopy is performed with a two-lens system that duplicates the two-eye perception of 3D. In this way binocular vision is maintained. The most commonly used 3D vision system currently in use is the InSite Vision System (Intuitive Surgical), which provides vision for the da Vinci Robotic System. The laparoscope and high-definition camera are controlled by a robotic arm that is under direct control of the surgeon from the ergonomic console. The surgeon maintains a steady, magnified 3D view of the surgical field. Zero- and 30-degree lenses are currently available.

Instrumentation for Grasping and Blunt Dissection

Most graspers and dissectors are used in their 5-mm size but are available in a range from 3 to 12 mm in predominantly reusable forms. Grasping instruments have either single-action (only one jaw moves during opening) or double-action (both jaws move) tip design.

Wide variations exist with regard to configuration of tip, surface characteristics of jaws, handle design, and possible electrosurgical properties. Tip designs include blunt-coarse, pointed (dolphin), straight (duckbill), curved (Maryland), and angled. The surface of the jaws may be atraumatic or traumatic. Serrated or smooth surfaces allow gentle tissue manipulation in atraumatic graspers (e.g., bowel forceps with a 3-cm long grasping jaw). Traumatic graspers have toothed or clawed surfaces on their jaws to allow them to grasp and hold tissues firmly. In addition, each of these instruments may be equipped with tip-rotation and/or articulating features. Reusable and disposable instruments are available.

Depending on the design of the handle, grasping instruments may be locking or nonlocking. Most nonlocking forceps have a scissor-type handle. Different designs allow for locking capabilities; in particular, bar-type and spring-loaded locking handles are convenient when prolonged grasping of tissue is required, whereas other dissectors offer additional degrees of freedom by means of an articulating joint activated through wrist movements of the surgeon.

In addition to standard dissecting instruments, the laparoscopic suction apparatus and the “heel” of the hook electrode can be used for effective and rapid blunt dissection. Along these same lines, laparoscopic “peanuts” or Kittners (i.e., 5- and 10-mm gauze-tipped disposable dissectors) have been most helpful. These dissectors can be moved side to side or up and down in an area of adipose tissue to rapidly tease away the fat surrounding vital structures such as the renal hilum or the adrenal gland. In addition, the device can be used to raise an entire “line” of tissue (e.g., pararenal fat), allowing for its rapid and safe division because neither the shaft nor the tip of the Kittner will conduct electrosurgical current.

Instrumentation for Incising and Hemostasis

Laparoscopic scissors, scalpels, electrocautery, ultrasonic devices, and lasers (CO_2, neodymium:yttrium-aluminum-garnet [Nd:YAG], or potassium titanyl phosphate [KTP]) are used to incise or cut tissue during laparoscopic surgery. Cutting of tissue with electrocautery and lasers is achieved when the cell temperature is elevated until the concomitant gas pressure causes the cells to explode. Conversely, with ultrasonic devices the cutting mechanism is a relatively sharp blade, vibrating at 25 kHz to 55 kHz over an excursion distance of up to 100 µm.

Monopolar and bipolar electrocautery and other technologies exist for achieving hemostasis. The basic mechanism for coagulating bleeding vessels is similar among the various modalities in that vessels are sealed and occluded with denatured protein; however, the manner in which protein is denatured is different for each modality. Electrosurgery and lasers denature protein by heating the tissues with electric current in the former and light in the latter at a very high temperature. Conversely, ultrasonic devices denature protein by transferring mechanical energy to ultrasonic high-frequency vibration (25 kHz to 55 KHz).

Sharp Dissectors.

Laparoscopic scissors are available in disposable and nondisposable forms. The blades of laparoscopic scissors are shorter than their open surgical counterparts. The configuration of the tip may be useful for selected situations: hooked tips for cutting sutures, microscissors for spatulating the ureter during a pyeloplasty, and curved tips for dissection. The scissors may come with either permanent blades or with replaceable tips; use of the latter ensures "sharp" scissors for each procedure. In addition, the shaft of the scissors may rotate and, in some disposable scissors, even articulate up to 90 degrees.

Monopolar Electrosurgical Devices.

For **electrosurgical incision** of tissue, a selection of different electrodes are available. Needle electrodes (Corson type) produce fine cuts useful in making peritoneal incisions. Spatula electrodes are used in blunt dissection and cutting. Hook electrodes (J and L configurations) are of particular value during dissection of vessels because tissue can be pulled away from delicate structures before the cutting current is activated. **The thinner the metal tip of the probe is, the higher the density of the electrical current, and the greater the tissue vaporization and apparent "cutting" power.**

As with all insulated instruments, certain precautions must be followed during monopolar electrosurgery to avoid local or distant transmitted thermal injury. Consequently, **the electrosurgical probe should not be activated unless the metal part is in complete view. The insulation of the electrosurgical instrument should be carefully checked for any damage. The probe should not be activated unless it is in direct contact with the tissue to be incised.**

To avoid the potential dangers of stray current from use of monopolar electrosurgical equipment, the surgeon can use monopolar current in conjunction with active electrode monitoring (Encision, Boulder, CO). This instrumentation is constructed so that there is ongoing feedback during activation of the electrosurgical current; therefore any break in the insulation of the shaft results in immediate deactivation of the instrument.

Bipolar Electrosurgical Devices.

The laparoscopic surgeon can also use bipolar electrosurgical devices that require less energy for performance than their monopolar counterparts. There is also a decreased likelihood of injury to surrounding tissue for a couple of important reasons. First, because the **electrical current is only passing from**

one jaw of the instrument to the other, it precludes the potential problem of capacitive coupling, common with monopolar electrosurgical current. Second, **with bipolar current, the extent of coagulative damage is less than with monopolar electrosurgery**: 1 to 6 mm versus 5 to 7 mm with monopolar current (Landman et al., 2003a).

One of the currently available bipolar electrosurgical devices is the LigaSure vessel-sealing system (Medtronic, Minneapolis, MN). It consists of a 5- or 10-mm grasper-dissector connected to a bipolar radiofrequency generator. When the vascular structure is grasped by the instrument, the tissue is evaluated by an impedance-based feedback-response system that subsequently delivers the optimal energy required to seal the vessel effectively. Because of the high-current and low-voltage output, the vascular structure enclosed by the jaws of the instrument degrades quickly, and a protein-based seal is presumably created. This mechanism of electrical current delivery to the tissues results in less charring and less collateral thermal damage (1–3 mm) (Landman et al., 2003a). Indeed, use of this instrument during partial nephrectomy does not compromise the ability of the pathologist to read the surgical margin (Phillips et al., 2008). An audible signal alerts the surgeon that the sealing of the vessel is complete; the instrument has a trigger-activated blade that the surgeon can then use to cut the sealed tissue. Vessels up to and including 7 mm in diameter appear to be effectively occluded to above-normal physiologic pressures with this device (Carbonell et al., 2003; Landman et al., 2003a). However, only one LigaSure application to the structure being sealed is recommended, because multiple applications may weaken the seal (Truong et al., 2008). An alternative to the LigaSure is the EnSeal G2 (Ethicon, Somerville, NJ), which is also a vessel-sealing and cutting device. This is a 5-mm instrument that can also act as a grasper-dissector and be used to seal vessels up to 7 mm.

In a recent study, surgical metrics including transection time, vessel-sealing time, thermal spread, and seal burst pressures were compared using five contemporary energy-based vessel-sealing devices (Okhunov et al., 2018). In their porcine model the Caiman 5 (Aesculap, Center Valley, PA) outperformed all devices tested. The Caiman 5 is a novel device that uses advanced bipolar technology with a pivoting jaw design and closing mechanism with the sealing electrodes distributed in the upper and lower jaws of the instrument (eFigs. 14.18A and B). This mechanism allows for a more homogenous pressure distribution in the jaws.

EFIG. 14.18 (A) Example of a Caiman 5 vessel-sealing system. (B) Caiman 5 tip. (Courtesy Aesculap, Center Valley, PA.)

Laser Instrumentation.

Lasers are most frequently used through the working channel of an operating laparoscope. The CO_2 laser provides excellent cutting and vaporization of surface lesions and requires a rigid hand piece and probe. In contrast, the 400- and 600-µm KTP fibers are flexible and allow for noncontact cutting and fulguration. Nd:YAG laser fibers are also flexible and allow noncontact fulguration and contact cutting. Holmium laser fibers are also flexible and are used in a contact mode for cutting. Typically, lasers are not used in urologic laparoscopy, where they have largely been supplanted by electrosurgical instruments. Only in gynecology is the CO_2 laser used extensively, generally in the treatment of endometriosis.

Ultrasound Instrumentation.

Ultrasonic technology (Harmonic scalpel [Ethicon, Sommerville, NJ]; Sonicbeat [Olympus, Center Valley, PA]; Sonicision [Medtronic, Minneapolis, MN]) is another option for cutting and hemostasis in endoscopic surgery. It provides an especially attractive alternative to monopolar electrosurgery for working around particularly delicate tissues or operating on patients with an implanted pacemaker or cardioverter defibrillator (Gossot et al., 1999; Strate et al., 1999). In ultrasonic devices, electrical energy is transformed into mechanical energy by the use of a piezoelectric crystal system. Specifically, electrical energy is produced by a power-supply generator and transformed into mechanical vibration at the tip of the instrument through a piezoelectric crystal interface (Gossot et al., 1999; Suzuki et al., 1995; Takeda et al., 1997). Mechanical vibrations produced by this system in the tip of the instrument are capable of causing cavitation, coaptation, coagulation, and cutting in the targeted tissue (Strate et al., 1999). There are several important benefits to the ultrasonic system. These include the absent risk of local thermal damage and tissue charring because of a working temperature lower than 80°C. Subsequently, reduced tissue charring may result in a reduced rate of postoperative adhesions (Amaral and Chrotstek, 1997). A second benefit is that the depth of penetration is limited to the targeted tissue within a diameter of 1 mm, so there is minimal lateral thermal spread and potential for tissue damage (Landman et al., 2003a). Ultrasonic devices also minimize smoke for improved visibility in the surgical field. In addition, the ultrasonic systems eliminate other problems associated with monopolar electrosurgery, specifically problems of remote site tissue damage caused by capacitive coupling, insulation defects in the instrumentation, and direct coupling. As with bipolar energy, use of ultrasonic energy during partial nephrectomy does not compromise the ability of the pathologist to read the surgical margin (Phillips et al., 2008). Last, cordless versions of these devices (e.g., Sonicision), although heavier, reduce the number of cords in the operative field.

Potential disadvantages of ultrasonic technology include slower vessel sealing (Lamberton et al., 2008) and the fact that the metal portion of the shears becomes hot during activation (often more than 200°C compared with the bipolar energy–based devices, which stay below 100°C) and must not come into direct contact with any bowel surrounding the area of dissection. In fact, the harmonic shears take roughly twice as long to cool to a “safe” temperature after firing (often up to 45 seconds) compared with the LigaSure device (Medtronic, Minneapolis, MN) (Kim et al., 2008).

Combined Devices and Other Instrumentation.

The Thunderbeat (Olympus, Center Valley, PA) combines ultrasonic and advanced bipolar energies into a single multifunctional instrument, allowing surgeons to seal and cut vessels up to and including 7 mm in size with minimal thermal spread. Initial studies have shown promising results, with the Thunderbeat surpassing the dissection speed of ultrasonic devices while having the sealing efficacy of bipolar devices (Milsom et al., 2012; Milsom et al., 2015; Seehofer et al., 2012).

The **argon beam coagulator** provides a noncontact form of electrocoagulation. Electrical current originating from a monopolar electrosurgical generator is conducted to the tissue through an ionized argon gas stream. The gas stream blows away blood from the tissue, resulting in better exposure of the bleeding site and therefore more effective delivery of the electrosurgical current. Argon is a colorless, odorless, inert gas that clears the body within one respiratory cycle (Quinlan et al., 1992). Holding the hand piece at an oblique 60-degree angle within 1 cm of the surface of the target tissue provides optimal coagulation effects. During argon beam coagulation, the sidearm on one of the laparoscopic ports must be opened to prevent buildup of excessive intra-abdominal pressures. Because argon beam coagulation has its major advantage when hemostasis must be achieved over a diffusely bleeding surface, its most practical indication in laparoscopic urologic surgery is during partial nephrectomy or for control of small liver or spleen lacerations.

Surgical Pharmaceuticals

Recently, a vast array of topical hemostatic agents and sealants that can be used for a variety of surgical tasks have entered the surgical realm and have become valuable additions to the surgeon's tray.

Fibrin-Based Glue.

Fibrin glue has been used to promote hemostasis in parenchymal beds, in particular after partial nephrectomy or to seal a liver laceration. The two components of the fibrin glue, fibrinogen and thrombin, are delivered through separate channels and then combine at the tip of the delivery system during application to the tissue. Fibrin glue provides topical hemostasis and has sealant and adhesive qualities once dry; it essentially hardens into a rubbery coagulum.

Tisseel VH Fibrin Sealant (Baxter, Glendale, CA) has the maximum concentration of human fibrinogen available (75–115 mg/mL). It can be delivered by means of a laparoscopic applicator in liquid form or in an aerosolized form. One disadvantage of Tisseel is that it requires 15 minutes to prepare before the surgeon can apply it. If immediate application is required (e.g., because of bleeding), then fibrin glue is not a viable option unless it has been prepared in anticipation of possible hemorrhage. Once prepared, Tisseel is available for use for 4 hours.

Another fibrin-based sealant that can be delivered as a spray is Evicel (Johnson & Johnson, New Brunswick, NJ). This agent contains no bovine serum components (e.g., aprotinin) and can be used in individuals with allergies to bovine-derived products. Another advantage of this sealant is it comes frozen and thus requires no reconstitution. It can be thawed in the hand in 5 minutes and available in another minute. Once thawed, Evicel has a shelf life of 1 month under refrigeration (Tredree et al., 2006). This product can also be applied laparoscopically or robotically with an available applicator.

Relatively new on the market is Evarrest (Ethicon, Somerville, NJ), a fibrin sealant patched embedded with human biologics. This product does not require preparation, mixing, moistening with saline, or refrigeration and has a shelf life of 30 months. Randomized control trials have shown superiority over topical absorbable hemostat agents (Fischer et al., 2013); however, as with most new agents, cost remains a concern.

Non–Fibrin-Based Surgical Hemostats.

In contrast to the fibrin-based agents, other hemostatic agents such as thrombin-soaked oxidized cellulose particles (Floseal [Baxter, Glendale, CA]; Surgiflo [Johnson & Johnson, New Brunswick, NJ]) have no adhesive capability but are excellent hemostatic agents in the presence of active bleeding from parenchymal surfaces such as a partial nephrectomy bed, a liver or spleen laceration, or an oozing adrenal bed. These agents are composed of human-derived thrombin and bovine- or porcine-derived gelatin matrix. The gelatin granules swell 10% to 20% to produce a tamponade effect, whereas the high concentration of thrombin promotes conversion of fibrinogen to fibrin, as well as activating platelets and several coagulation factors. This agent is also prepared by the scrub assistant; it takes 2 minutes to prepare and is usable for 2 hours. It is applied through a tube applicator with a syringe. It is most effective when pressure is applied after its delivery; this can be done either with an instrument (e.g., 10-mm gauze-tipped dissector) or with a bolster.

The Avitene microfibrillar collagen hemostat (Davol, Cranston, RI) is an active collagen hemostat that accelerates clot formation by enhancing platelet aggregation and the release of fibrin. Similar to Floseal, it has no tissue sealing capability but is useful for counteracting parenchymal bleeding. EndoAvitene is available for use in endoscopic procedures. EndoAvitene comes prepared in a preloaded endoscopic delivery system developed to easily pass through standard trocars and cannulae. It is available in 5- and 10-mm diameters.

Chemical-Based Sealants.

BioGlue (CryoLife, Kennesaw, GA) is a two-component adhesive composed of purified bovine serum albumin (BSA) and glutaraldehyde. The solutions are mixed during application from a controlled delivery system. The glutaraldehyde then cross-links the BSA molecules to one another and then to the tissue protein at the site of use. Once applied, the agent polymerizes within 20 to 30 seconds and reaches its full bonding strength within 3 minutes. The delivery system comes ready for immediate use. BioGlue is a sealant and must be applied to a dry field and allowed to dry. Thus it cannot be used to counteract active bleeding but can be used to seal a raw, nonbleeding surface.

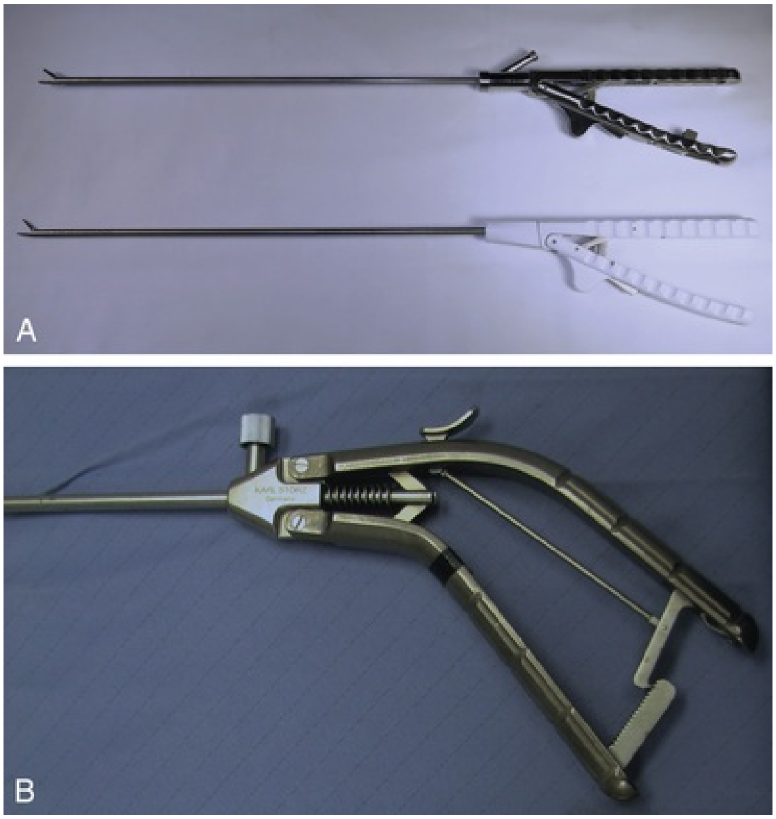
Coseal (Baxter, Glendale, CA) and AdvaSeal-S (Genzyme, Cambridge, MA) are completely synthetic products composed of two distinct polyethylene glycol polymers that chemically bond together to form a hydrogel that seals tissue surfaces, suture lines, and synthetic grafts. It does not require thawing, heating, or light activation and therefore can be ready in 1 minute. It must be applied to a dry (nonbloody) surface because it does not interact with the clotting cascade and therefore is not useful in the setting of active hemorrhage.

Now that the benefits of such substances have come into the spotlight in surgery, it is important for the surgeon to be familiar with the properties of these various agents and thereby able to choose one that is most appropriate for the job at hand.

Instrumentation for Suturing and Tissue Anastomosis

Needle Drivers.

Suturing and knot tying are among the most difficult tasks in laparoscopic surgery. A significant amount of practice is needed to achieve a sufficient level of proficiency. **Laparoscopic needle holders** have one fixed jaw and one jaw that opens by squeezing the spring-loaded handle of the instrument. They all have a locking mechanism to secure the needle in their jaws; this is done with a ratchet, spring-loaded, or Castroviejo-type mechanism. Some needle holders also possess a feature that allows the jaws to rotate around the main axis relative to the handle. The handles may be straight or provide a pistol-type grip (eFig. 14.19). In addition to standard rigid needle drivers, some companies have recently developed articulating needle drivers that aid in obtaining more optimal suturing angles with the needle. The actuation of the articulation mechanism is controlled by the surgeon's wrist motion (Laparo-Angle, Cambridge Endoscopic Devices, Framingham, MA).



EFIG. 14.19 Different handle designs for commonly used laparoscopic needle drivers. (A) Straight-handled reusable *(top)* and disposable *(bottom)* drivers. (B) Pistol-type grip.

Endo Stitch.

The Endo Stitch (Medtronic, Minneapolis, MN) device is a disposable, 10-mm instrument that facilitates laparoscopic suture placement and knot tying (Adams et al., 1995). With increased experience with standard laparoscopic needle holders and especially with the advent of robotic-assisted procedures, use of the Endo Stitch has become less common.

The suture is secured to the center of a straight needle with two pointed ends, thereby allowing tissue penetration in either direction. The needle is shuttled back and forth between the jaws of the instrument after each passage through the tissue, applying a long-known principle used in sewing machines. In this way, passing the needle through the tissue and regrasping the needle after it has traversed the tissue become simple tasks because they are done by a one-handed squeeze of the handle and a flip of the needle-securing lever, respectively. Use of this sewing apparatus has had a major impact on decreasing operative times, especially in laparoscopic pyeloplasty (Chen et al., 1998).

Lapra-Ty Clips.

Lapra-Ty clips (Ethicon, Somerville, NJ) are a very useful adjunct to suturing and knot tying. **The clip acts as a knot, thereby precluding time-consuming intracorporeal laparoscopic knot tying** (Fig. 14.20). These 3.5-mm clips are made of absorbable polydioxanone and are designed to provide secure anchoring of sutures for up to 14 days in low-tension to mid-tension environments (Ames et al., 2005). According to the manufacturer, these suture anchors can be secured to the end of a single strand of polyglactin 910 (Vicryl) suture as fine as 4-0. Experimental models from two different laboratories have shown that these clips are least likely to fall off polyglactin 910 sutures from size 1-0 to 3-0 (Ames et al., 2005; Weld et al., 2008). In the laboratory environment Lapra-Ty clips have been shown to be slip resistant with 2-0 Monocryl and polydioxanone suture. In multiple test trials for each suture type, a percentage of monofilament sutures size 3-0 and smaller as well as 4-0 suture of any type had slippage of the clip. Therefore it seems logical to avoid Lapra-Ty use with 4-0 suture and to avoid excessive tension when using these clips with 3-0 monofilament suture. Lapra-Ty clips can be used to secure a single suture or a running suture and for anchoring bolsters during renorrhaphy for laparoscopic or robotic partial nephrectomy (Orvieto et al., 2004).

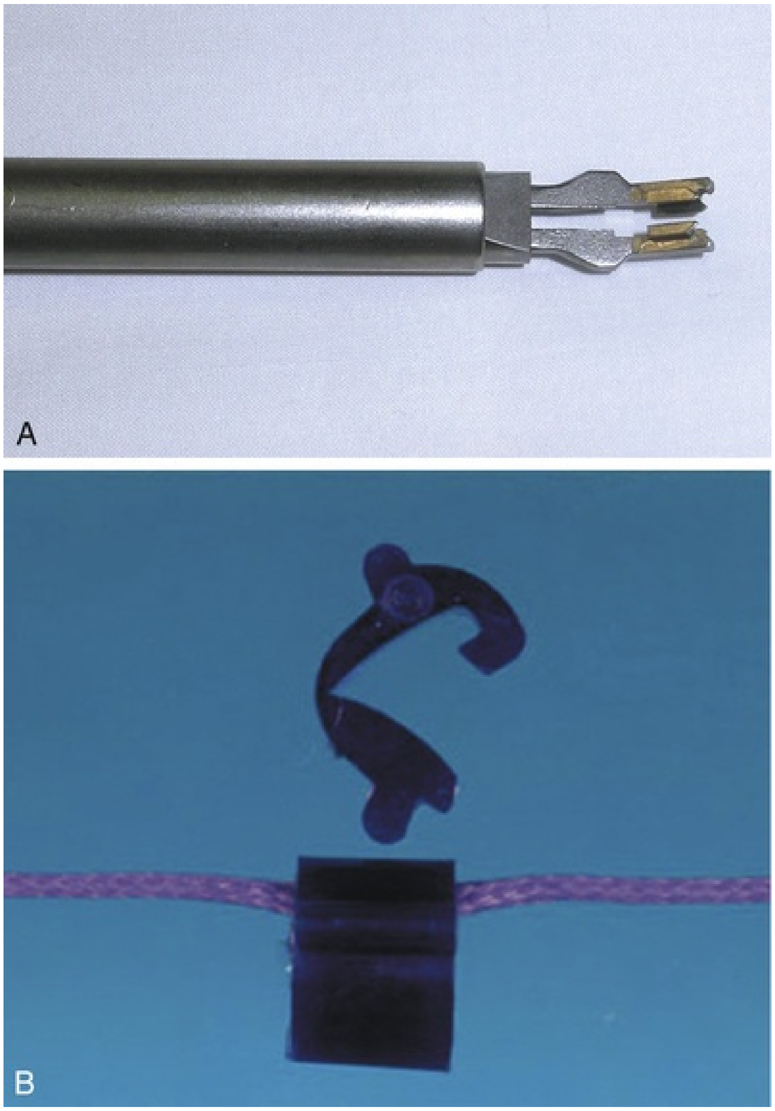


FIG. 14.20 (A) Tip of a laparoscopic device for applying a Lapra-Ty clip (Ethicon, Somerville, NJ). (B) Lapra-Ty clip affixed to a suture.

Barbed Suture.

The knotless barbed suture (V-loc; Medtronic, Minneapolis, MN) is an innovative type of suture that can accelerate the placement of sutures and eliminate knot tying (Fig. 14.21). The specifically designed monofilament suture with barbs orientated in the opposite direction of the needle allow the suture to grab the tissue without allowing the suture to slide back. The use of barbed suture was initially popularized for use during the vesicourethral anastomosis during robotic prostatectomy (Zorn et al., 2011); however, given the versatility of the suture, its use has expanded across the range of urologic surgery. A recent meta-analysis indicates that the vesicouretheral anastomosis using barbed suture was associated with a shorter operative time, comparable complication rate, and convenience of manipulation (Bai et al., 2015).

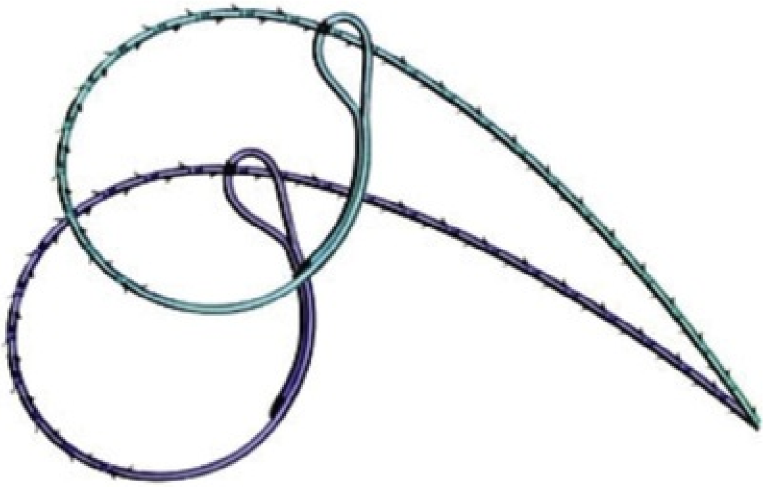

FIG. 14.21 Knotless barbed suture. (Courtesy Medtronic, Minneapolis, MN.)

Instrumentation for Stapling and Clipping

Stapling Devices.

Various stapling devices are available for tissue occlusion and division. The Endo GIA Universal 12-mm stapler and linear cutting device (Medtronic, Minneapolis, MN) requires a 12-mm port and delivers two triple-staggered rows of staples and simultaneously cuts between the rows (Fig. 14.22). The Universal stapler can be loaded with a variety of 30-, 45-, or 60-mm loads and fired any number of times. Similarly, the ETS-Flex 45 stapler (Ethicon, Somerville, NJ) also requires a 12-mm port and delivers two triple rows of staples while cutting between rows 3 and 4. This stapler has a maximum fire limit of eight staple loads. Articulating and roticulating staplers that enable the surgeon to properly align the instrument with the tissue to be occluded and divided are available from both companies. **Each staple load cartridge is color coded depending on the size of the staples: 2.0-mm staples (gray) or 2.5-mm staples (white) are preferred for vascular (renal vein or renal artery) stapling, whereas 3.8-mm (blue) and 4.8-mm (green) staples are used in thicker tissues (ureter, bowel, bladder).** In addition, for laparoscopic live donor nephrectomy, a single Endo-

TA (linear noncutting) stapler can be used to secure the patient's side of the renal vein, thereby providing a longer donor renal vein, because there is no need to trim staples from the vessels before anastomosis in the recipient (Meng et al., 2003). Linear noncutting staplers deliver either three or four staple rows 30 or 60 mm long. These staplers can also be used to close an enterotomy after a side-to-side bowel anastomosis. **When laparoscopic staplers are used, special attention must be paid to the markers on the cartridge to ensure that all the targeted tissue is properly situated proximal to the markers before the cartridge is fired. The stapler should not be fired across any previously placed clips because this is thought to possibly cause stapler malfunction.** Indeed, in a 9-year review of stapler use (1992 to 2001), Brown and Woo (2004) noted US Food and Drug Administration–recorded reports of 112 mortalities and 2180 injuries attributed to use of the stapler; overall, malfunctions were reported 22,804 times.

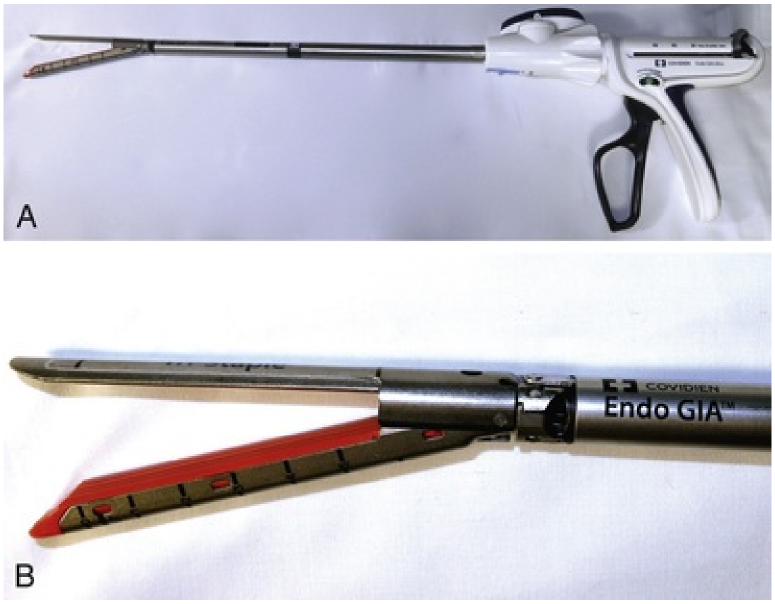

FIG. 14.22 (A) Example of Endo GIA laparoscopic stapling device. (B) Stapling device tip. (A, Courtesy Medtronic, Minneapolis, MN.)

The first powered stapler was introduced in 2010. Currently the iDrive Ultra (Medtronic, Minneapolis, MN) and the Echelon Flex GST System (Ethicon, Somerville, NJ) are the most widely available (Fig. 14.23). Powered staplers are thought to increase the stability and enable more precise stapling relative to manual staplers. In a large-study retrospective review in bariatric surgery, better economic outcomes and a lower rate of bleeding was noted in the powered staplers group (Roy et al., 2017). Further, prospective, randomized trials are needed to support these findings.

Clipping Devices.

Disposable and nondisposable clip appliers are available from different manufacturers and require 5-, 10-, or 12-mm laparoscopic ports. In general, they contain occlusive clips ranging in size from 6 to 11 mm. Disposable clip appliers possess a rotating shaft and multifire, self-reloading features, whereas nondisposable instruments have to be reloaded for each clip to be deployed at the site of surgery.

Electrocoagulation must be avoided in the vicinity of clips placed for occlusion of vessels to prevent conductive tissue necrosis and subsequent clip dislocation. To ensure reliable function, the closed ends of the occlusive clips must be seen extending slightly beyond the targeted vessel and should be placed perpendicular to the longitudinal axis of the vessel.

In addition to titanium clips, polymer clips that completely encircle and lock down around a vessel are available (Weck Hem-o-lok polymer ligation clip system [Teleflex, Research Triangle Park, NC]) (Fig. 14.24). They are available in four sizes (M, ML, L, and XL). Up to 10 mm of tissue can be ligated through a 5-mm trocar, and up to 16 mm of tissue can be ligated through a 10-mm trocar. Because of results from a survey put forth by the American Society of Transplant Surgeons in which use of these clips was associated with hemorrhage from the renal artery stump, the company producing the clips put forth a statement contraindicating their use for securing the renal artery during laparoscopic live donor nephrectomies (Friedman et al., 2006). Subsequently, a multi-institutional study of 1695 patients from 9 different institutions undergoing laparoscopic donor nephrectomy with ligation of the renal artery with Hem-o-lok clips concluded that the clips were safe to use because in this review there were no adverse bleeding events (Ponsky et al., 2008a). **The authors did acknowledge, however, that proper technique of application must be strictly adhered to, including application of at least two clips on the stump of the artery and that a 2-mm cuff of artery should be left distal to the clips** (Box 14.2). Removal of a Hem-o-lok clip is possible using the specified removal instrument should a structure be clipped in error.

Box 14.2

Basic Principles of Hem-o-lok Clip Placement

- Complete circumferential dissection of the vessel
- Visualization of the curved tip of the clip around and beyond the vessel, often with the curved end of the clip placed between the artery and vein
- Confirmation of the tactile snap when the clip engages
- No cross-clipping
- Not squeezing the clip handles too hard (compared with the application of metal clips)
- Careful removal of the applier after application is given; the tips are sharp and can cause a laceration of nearby vessels (e.g., renal vein)
- During transaction of vessels, only a partial division is performed initially to confirm hemostasis before complete transaction
- Minimum of two clips are placed on the patient side of the renal hilar vessel

Instrumentation for Specimen Entrapment

Various organ entrapment and retrieval systems are available. Depending on the size of the tissue and on whether in situ morcellation or intact organ retrieval is planned, the laparoscopic surgeon can choose among different-sized sacks, materials, and designs. Studies have been conducted to test organ retrieval bags for permeability to tumor cells and bacteria before and after morcellation, as well as for stability during morcellation and resistance to tearing forces (Rassweiler et al., 1998b; Urban et al., 1993). The originally designed (1990) LapSac (Cook Urological, Spencer, IN), which is made of nylon with a polyurethane inner coating and a polypropylene drawstring, is the entrapment sack least susceptible to tearing (Eichel et al., 2004) or leakage of cells. Up to a 2-kg specimen can be secured within the LapSac; however, deployment of the LapSac and subsequent organ entrapment are challenging.

Other entrapment sacks offer marked advantages when the only goal is organ entrapment and intact removal rather than morcellation. These sacks have spring wires that, when activated by the surgeon, deploy the bag after its introduction into the abdomen; this facilitates tissue entrapment because the broad wire supports stabilize the opened sack, thereby allowing the surgeon to scoop the specimen into the sack (Fig. 14.25). The entrapped specimen can easily be withdrawn through a hand-assist site or by enlarging a laparoscopic port site, usually to 5 to 7 cm for most specimens.

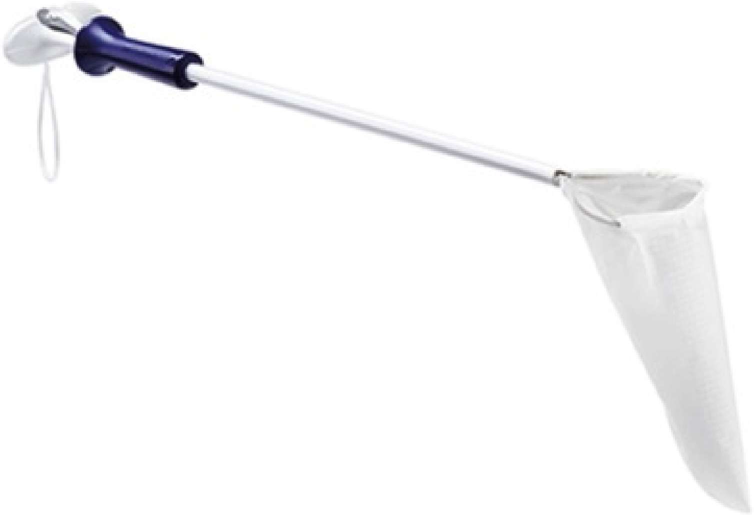

FIG. 14.25 Example of an organ retrieval bag. (Courtesy Medtronic, Minneapolis, MN).

Instrumentation for Morcellation

Various techniques of tissue morcellation have been used in laparoscopic surgery. The simplest method for fragmentation of tissue within the entrapment sack is use of the index finger, ring forceps, or Kelly clamp. The ring forceps are the preferred instrument for manual morcellation because they are less likely to puncture the entrapment sack (Eichel et al., 2004).

If morcellation is performed intracorporeally, the entrapment sack should be a LapSac; however, a variation reported by Landman et al. (2003b) for morcellation uses one of the plastic entrapment sacks. In this method, the morcellation is performed above the abdominal wall by extending the extraction site incision to 3 cm in length. **All tissue is fragmented and removed under direct vision above the abdominal surface; at no time is the morcellating instrument out of the direct vision of the surgeon.** With this approach, specimens could be morcellated rapidly, with the entire entrapment and morcellation process taking only 13 minutes for clinical specimens as large as 700 g; also fragment size increased from 1.5 to 4.5 g, which may afford better tissue assessment with regard to capsular, vascular, or renal sinus fat invasion (Landman et al., 2003b).

For morcellation of a renal malignancy, the neck of the sack is triply draped to preclude any contamination: a towel drape, Ioban (3M, St. Paul, MN), and nephrostomy drape can be used. At the end of the morcellation procedure, the surgeon and assistants regown and glove.

The use of an entrapment sac is important because wound seeding with tumor has been reported with intact specimen extraction without entrapment (Iwamura et al., 2004). In contrast, there has been only one noted wound seeding with morcellation in a LapSac (Fentie et al., 2000). A multi-institutional study comprising 2064 radical nephrectomies, among which 826 were removed by entrapment and morcellation, showed no instance of a wound seeding with tumor (Micali et al., 2004).

Instrumentation for Retraction

Many varieties of retractors with different features are available.

The simplest retractor is a metal bar with an atraumatic tip or a curved saddle shape; the latter is helpful for retracting a vessel during lymph node dissection. Similarly, the disposable laparoscopic "peanut," in either its 5- or 10-mm rendition, is very helpful because it can dissect and atraumatically retract tissue.

However, the most useful retractors are the expanding types: fan retractors with three or four atraumatic fingerlike extensions, fan retractors with V-hinge joints, balloon retractors, and kite-style instruments (e.g., Padron endoscopic exposing retractor) (Jarit, Hawthorne, NY) (Brooks, 1993). The 5-mm kite style retractor provides a 2- × 3-cm retracting area, whereas the 10-mm version provides a 4- × 3-cm retracting area. This type of retractor is very helpful for firm retraction, such as on the kidney to put the renal hilum on stretch.

Another type of retractor is malleable and thus can be shaped to the needs of the surgeon. The Diamond-Flex angled 80-mm triangular retractor (Snowden-Pencer Instrumentation, Carefusion, Waukegan, IL) can be adapted to many different angles, curves, and shapes, and the surgeon can lock in its particular configuration. This feature is of particular value when retraction of a delicate organ such as the liver is required. This instrument forms a broad retracting surface 8 cm in length.

Retraction of tubelike structures (e.g., vessels, ureter) can also be achieved by placing a suture, a vessel loop, or an umbilical tape around the tissue and applying traction either with a grasper inside the abdomen or by pulling the ends of the retraction loop out of the abdomen through a small stab incision using a Carter-Thomason device (Carter, 1994) or by encircling the structure with a suture affixed to a Keith needle, which can be passed across the abdominal wall, around the structure to be retracted, and then back out the abdominal wall (see following discussion of exiting the abdomen). The retraction loop can then be secured under slight tension on the surface of the abdomen with a small hemostat. Care should be taken during the use of this technique because excessive tension may injure the structure being retracted.

Mechanical Assistants.

External mechanical devices such as the EndoHolder (Codman, Raynham, MA) or the Laparostat (Civco, Kalona, IA) can be used to keep grasping forceps or locking retractors in position, thereby taking the place of a tableside assistant. This device is usually mounted on the side of the table opposite the surgeon. The malleable-free arm is then affixed to the shaft of a grasping forceps or laparoscopic retractor. When the surgeon has used the retractor for its given purpose, the malleable arm of the external mechanical device is locked in place, thereby providing reliable, continued traction.

Robotic Instrumentation

For the da Vinci Robotic System (Intuitive Surgical, Sunnyvale, CA), a wide variety of articulating instruments are available. The proprietary EndoWrist (Intuitive Surgical, Sunnyvale, CA) technology offers articulation at the tip of the instruments with 7 degrees of freedom and 90 degrees of articulation, mimicking the wrist movements of the surgeon at the robotic console (Fig. 14.26). A full line of 8-mm EndoWrist instruments are available, but most robotic instruments for the da Vinci Surgical System (except the laparoscopes) have a 10-case limit before they must be replaced. The number of “lives” left on each instrument should be recorded with each case.

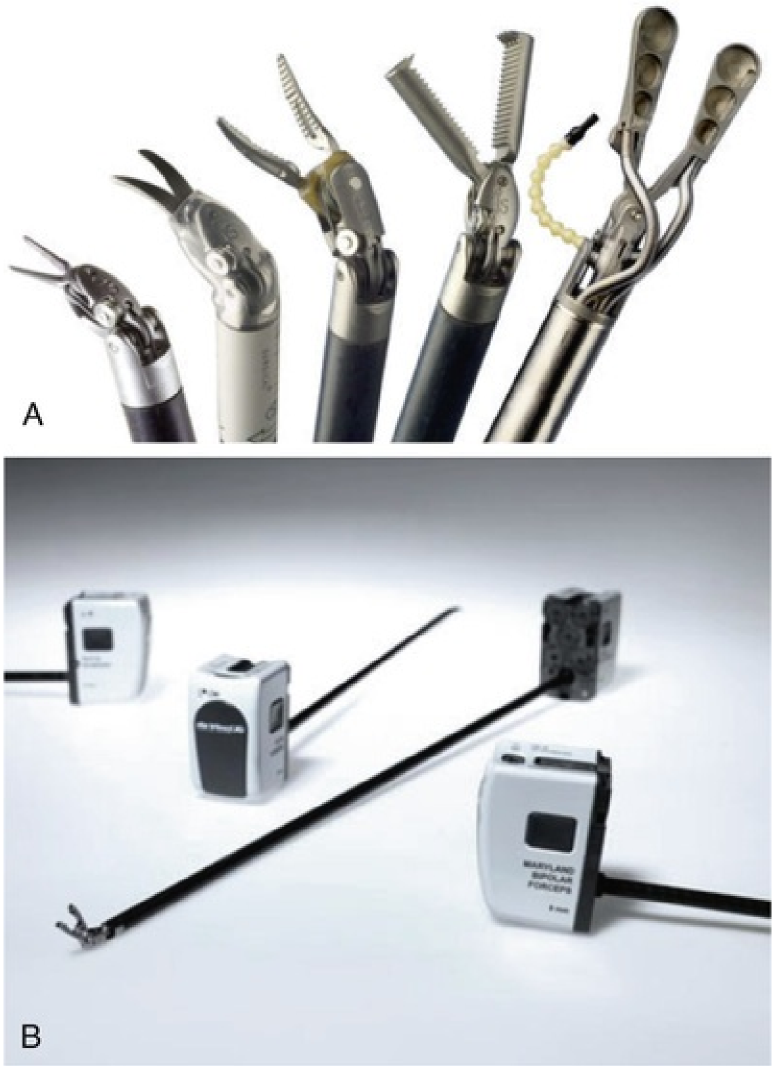

FIG. 14.26 A and B, Examples of 8-mm interchangeable instruments for the da Vinci Robotic System. (Copyright 2018 Intuitive Surgical, Inc. Used with permission.)

Instrumentation for Incising and Hemostasis

EndoWrist scissors for incising tissue include the round tip and Potts scissors. EndoWrist monopolar and bipolar electrocautery instruments are available for incision, dissection, and hemostasis during procedures. Monopolar instruments include the HotShears curved scissors, cautery hook, and spatula. Bipolar instruments include the Maryland, fenestrated, curved, micro, long, and vessel sealer. An ultrasonic device (Harmonic ACE curved shears, Ethicon, Somerville, NJ) is also available for dissection and hemostasis.

Instrumentation for Grasping and Blunt Dissection

A large array of EndoWrist graspers exist, including Prograsp, tenaculum, long-tip, tip-up fenestrated, small grasping retractor Cadiere forceps, Cobra grasper, dual-blade and resano forceps, for use in varying situations. The most commonly used grasper in urologic procedures is the ProGrasp blunt forceps.

A safety feature on all robotic grasping devices is a small Allen bolt that can manually open the jaws of the instrument in the case of a robotic arm malfunction or loss of power in which the grasper is locked onto tissue or a needle at the time of failure. Robot failure is rare. In the series from the University of Chicago, a robot failure was recorded in less than 1% of cases, and half of these problems (e.g., failure to power up, optical malfunction) were discovered before the patient entered the operating room. In addition, in the few instances in which there was a system malfunction (e.g., loss of 3D vision, robotic arm failure) during the case (0.4%), the procedure could still be completed without converting to an open procedure (Zorn et al., 2007).

Instrumentation for Suturing and Tissue Anastomosis

Four different EndoWrist needle drivers are available for suturing. There are two sizes of needle drivers available in the standard and SutureCut design. The SutureCut design allows the surgeon to be able to cut the suture material using the crotch of the instrument.

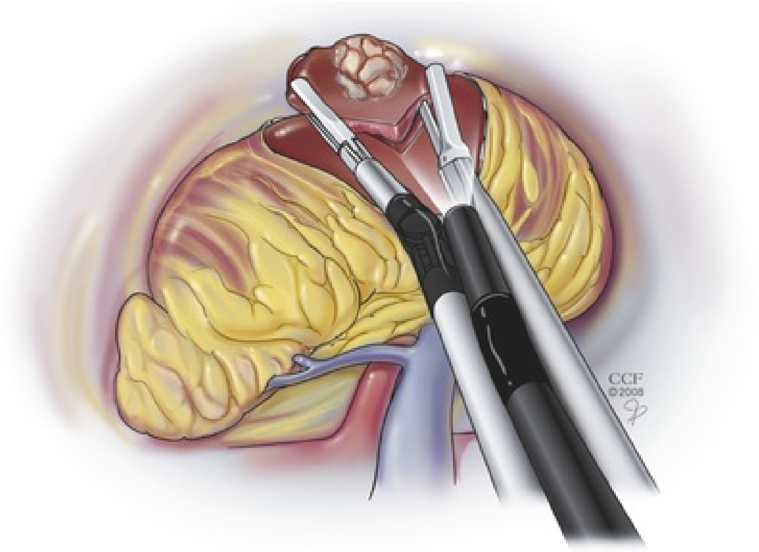
Other Available 8-mm and 5-mm Instruments

A number of other robotic instruments are also available. EndoWrist clip appliers exist for small titanium clips and medium-large and large Weck Hem-o-lok polymer clips (Teleflex Medical, Research Triangle Park, NC). In addition, an articulating suction device and irrigator, a probe stabilizer, and specialty retractors exist.

A 5-mm line of instruments is also available that is slightly more limited but still offers a relatively complete line of instruments. However, the 5-mm robotic laparoscope offers a 2D, not 3D, image.

Instrumentation for Single-Site Surgery

A detailed description of access devices for LESS such as the TriPort15/TriPort+ and SILS has previously been presented in this chapter. By definition, in LESS, all of the instrumentation for the case, including a camera and lens for visualization and the working instruments to perform the procedure, must be placed though a single incision. This creates ergonomic challenges with regard to instrument collisions inside and outside the abdominal cavity. Furthermore, the typical trocar arrangement for laparoscopy, which affords one the ability to "triangulate," is largely lost with LESS. Much of the emphasis on instrumentation for LESS, therefore, centers on minimizing instrument collisions outside the abdominal cavity and recreating the "triangulation" necessary to approach the surgical site safely (eFig. 14.27).



EFIG. 14.27 Deflecting laparoscopic instrumentation can be used to maintain triangulation during laparoendoscopic single-site surgery. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography, copyright 1998–2011. All rights reserved.)

With regard to endoscope choice, one issue encountered is that the light cord often attaches to the telescope at a 90-degree angle and can thus hinder the movement of the lens or other instruments. To avoid this problem the surgeon can use an endoscope that has the light cord attached end-on from the back directly into the endoscope (Karl Storz, Tuttlingen, Germany) or a one-piece endoscope that already has an end-on integrated light cord (EndoEYE, Olympus, Center Valley, PA). Alternatively, an extra-long laparoscopic lens can be used to keep the light cord away from the shorter standard working laparoscopic instruments. Similarly, use of laparoscopic instruments of different lengths can help keep the handles from clashing with one another.

With regard to overcoming the parallel nature of the instrument paths and reestablishing a triangular arrangement of instrumentation, several technologic advances have been developed so far with endoscopes and instruments. In terms of endoscopes, a laparoscope with a deflecting tip (EndoEYE Flex [Olympus, Center Valley, PA]) or adjustable angle tip (EndoCAMeleon [Karl Storz, Tuttlingen, Germany]) should be used because these telescope designs offer the greatest adjustability for optimal viewing. At the very least an angled lens (30- or 45-degree fixed angle) should be used. In terms of instruments, the use of articulating or curved instrumentation is essential to avoid instrument collision outside the abdomen and to achieve proper triangulation for tissue retraction, exposure, and dissection. Curved reusable laparoscopic instruments are also available (Karl Storz-Tuttlingen, Germany; Sklar Instruments, West Chester, PA) and provide a nondisposable alternative to the articulating instruments, which are one-time-use items. Single-curved and double-curved reusable instruments exist.

Finally, robotic laparoendoscopic single-site is currently being used for nephrectomy (partial, simple, and radical), pyeloplasty, nephroureterectomy, prostatectomy, and sacrocolpopexy (Nelson et al., 2017). Unfortunately, the robotic arms using the Gelport still resulted in limited triangulation angles, and this spurred the development of the new SP1098 platform, which is in the preclinical testing phase (Ramirez et al., 2016).

Instrumentation for Natural Orifice Transluminal Endoscopic Surgery

The concept of natural orifice transluminal endoscopic surgery (NOTES) is not truly new; indeed, the first NOTES procedure would have been Philipp Bozzini's cystoscopy in 1804. What is new is the use of flexible endoscopic technology to perform procedures heretofore unthinkable with a transgastric (e.g., appendectomy in 2004 by Rao and Reddy) or transvaginal approach (e.g., appendectomy in 2004 and cholecystectomy in 2007 independently by Bressler and then Marescaux). Over time these increasingly complex endoscopes have developed from purely diagnostic instruments for visualization of intraluminal surfaces to highly functional endoscopes capable of carrying therapeutic tools that can be used to treat visualized problems. Further advances in this type of technology have led to the development of endoscopes specifically for transluminal surgery. The potential advantages of transluminal endoscopic surgery are better cosmesis, less pain, elimination of the risk for wound infection and hernias, and a reduction in adhesions (Swanstrom et al., 2008a, 2008b).

Exiting the Abdomen

Port Removal and Fascial Closure

Port removal and fascial closure are key elements of the procedure that, if not performed in a step-by-step, organized fashion, can result in major, possibly fatal, complications. Herniation, possible bowel incarceration, and postoperative hemorrhage are the results of a poorly performed or haphazard, overly rapid exiting of the abdomen.

Before port removal is initiated, the operative site and the intra-abdominal entry sites of each cannula must be carefully inspected with the intra-abdominal pressure lowered to 5 mm Hg. After achievement of perfect hemostasis, removal of all laparoscopic ports must be undertaken strictly under laparoscopic visual control to avoid any possible acute herniation of intra-abdominal contents into the previous port sites.

Presently, with the shift away from bladed to nonbladed trocars, the need for fascial closure for even 12-mm ports has come into question. Most will recommend that **on removal of any of the blunt-tipped ports, the fascia does not have to be sutured, except for ports larger than 10 mm placed in the midline. However, a report has shown that 12-mm ports, regardless of site (i.e., midline vs. transmuscular), do not require fascial closure, provided that postoperative palpation of the entry site reveals a small defect** (Siqueira et al., 2004). **In the literature, the switch from bladed to blunt trocars has resulted in a marked decrease in abdominal wall bleeding (from 0.83% to only 0.16%) and in port site hernia formation (1.83% to 0.19%)** (Hashizume and Sugimachi, 1997; Thomas et al., 2003).

In the rare case in which bladed trocars are used, the fascia at all 10- to 12-mm port sites should be closed. After inspection at 5 mm Hg, the first 10- or 12-mm port is removed and the fascia at the entry site is secured with 0-0 Vicryl either by direct placement of a fascial suture or use of a suture-passing device (see following). **Five-millimeter ports are not closed in the adult but are closed in the pediatric patient with a single absorbable suture.** Ideally, each fascial suture will be placed under direct endoscopic vision before definitive port removal. In this manner, each port is visually assessed for any bleeding at 5 mm Hg, thereby precluding the possibility of removing a port and missing an injured vessel. After removal of all ports, the CO_2 is allowed to pass out passively through the 5-mm port sites.

The hand-assist device should be removed before removal of the other port sites. The hand-assist device wound is then closed as one would close a typical abdominal wound. After closure, the pneumoperitoneum is reestablished and the other port sites are closed as previously described. Proceeding in this fashion precludes the chance of injuring the bowel or omentum beneath the hand-port site and ensures an airtight closure.

Instrumentation for Port Site Closure

Several possibilities for fascial closure of port sites exist. The **simplest method** is retracting the skin with retractors, grasping the fascia, and suturing it with absorbable 0-0 suture. However, in patients with a BMI above 30, securely accessing the fascia is very difficult to accomplish.

Fortunately, several devices for complete en bloc closure of fascia, muscle, and peritoneum under direct vision have been developed (Carter, 1994; Elashry et al., 1996; Garzotto et al., 1995; Monk et al., 1994). These work well in patients of all sizes.

The **Carter-Thomason needle-point suture passer** (CooperSurgical, Pleasanton, CA) consists of a 5-, 10-, or 12-mm cone that has two integrated, hollow, angled, cylindric passages located 180 degrees opposite each other (Fig. 14.28). With the sharp needle-point, single-action grasper, the 0-0 Vicryl suture is inserted through one of the cylinders in the metal or plastic cone, thereby traversing muscle, fascia, and peritoneal layers in an ever-widening angle. The end of the suture is grasped with a 5-mm grasper through one of the other ports. The needle-point grasper is reintroduced through the other cylinder of the cone, and the intraperitoneal end of the suture is grasped by the needle-point grasper and pulled out of the abdomen. The cone is slid off both ends of the suture. Subsequently, closure of the fascia, muscle layer, and peritoneum is accomplished by tying the suture. **The Carter-Thomason needle-point device not only is helpful for wound closure but also can be used as a fifth port during nephrectomy to help hold the sack open or to encircle the ureter with a vessel loop through a small stab incision.**

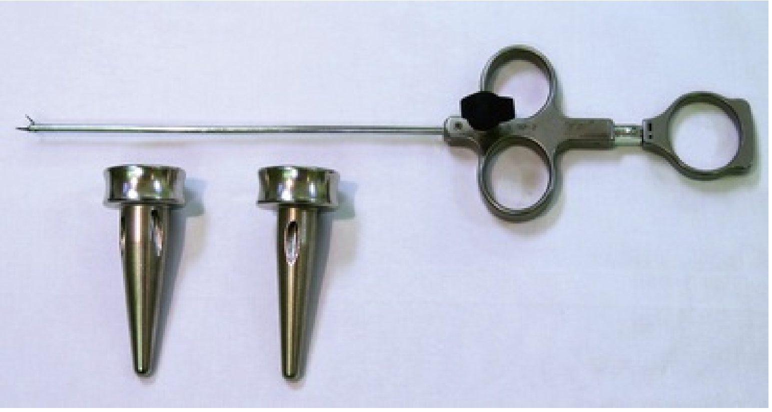


FIG. 14.28 Carter-Thomason device. Cone and needle-point single-action grasper in open position.

The disposable Endo Close suture carrier (Medtronic, Minneapolis, MN) is a device with a spring-loaded suture carrier at its tip. Loaded with a suture, the device traverses fascia, muscle, and peritoneum alongside the port. After reinsertion on the opposite side of port entry, it is reloaded with the suture, aided by a 5-mm grasper, and is pulled out again so that the suture can then be tied.

A far simpler, less expensive, homemade solution is available to all surgeons for closing ports in a large patient. This **angiocatheter technique** applies the previously described principles. A 14-gauge, sheathed needle is passed alongside the port through the abdominal layers. After removal of the needle, a 0-0 Vicryl suture is inserted through the angiocatheter sheath until it is deep inside the peritoneal cavity. After the sheath is removed, the same maneuver is repeated on the opposite side, but this time a 30-inch 0-0 Prolene suture folded in half is passed into the peritoneal cavity through the sheath to act as a retrieving loop. A 5-mm grasper passed through another port is then passed through the loop of 0-0 Prolene suture and used to grasp the end of the 0-0 Vicryl suture. The 0-0 Vicryl suture is pulled through the Prolene loop and released. By pulling the Prolene loop upward through the angiocatheter sheath, the surgeon then retrieves the entrapped 0-0 Vicryl suture from the abdomen. After the angiocatheter sheath is removed, the two ends of the suture can be tied.

Closure of the Skin

The skin of all 10-mm port sites is closed with subcuticular 4-0 absorbable suture. Adhesive strips are applied to all port sites to close (for incisions <10 mm) or to further approximate (for incisions ≥10 mm) the skin. As an alternative, the skin can be closed using octylcyanoacrylate glue. This has been found to speed closure time and provide an equivalent cosmetic result compared with suturing (Sebesta and Bishoff, 2004).

Key Points: Performing the Procedure

- A checklist ensuring that all essential equipment is present and operational should be completed just before initiating the pneumoperitoneum. Additional items to check when using the da Vinci Robotic System include ensuring that all plugs for the console, vision cart, and patient-side cart are plugged into different circuits and that all cables connecting these carts are connected properly.
- After placement of the Veress needle, insufflation should never be initiated unless all of the signs for proper peritoneal entry (negative aspiration, easy irrigation of saline, negative aspiration of saline, positive drop test result, and normal advancement test) have been confirmed.
- The open technique is recommended specifically when extensive adhesions are anticipated.
- Noncutting dilating trocars have superseded bladed trocars because they are safer. These trocars enter the abdomen by spreading the abdominal wall musculature, rather than cutting it, and therefore there is less chance of injuring an abdominal wall vessel, and the resulting entry site is less prone to subsequent herniation.

Physiologic Considerations in the Adult

Almost 30 years have passed since Clayman et al. performed the first laparoscopic nephrectomy. Since that time laparoscopy and robotics have become common in operative urology; therefore it is important to be familiar with physiology and the potential complications related to the pneumoperitoneum and patient positioning.

Choice of Insufflant

Carbon Dioxide

CO_2 is the most commonly used insufflant for laparoscopic and robotic surgery and is favored by most minimally invasive surgeons thanks to its properties (colorless, noncombustible, very soluble in blood, and inexpensive). Prolonged postoperative distention of the abdomen does not occur because CO_2 is quickly absorbed (Wolf and Stoller, 1994). It is highly soluble in water and easily diffuses in body tissues. It readily moves out of the peritoneal cavity as a result of a high diffusion gradient caused by the difference in concentration of CO_2 between the intraperitoneal space and the surrounding components (e.g., blood). However, the characteristic of rapid absorption, which lessens the chance of a CO_2 gas embolus, may also lead to potential problems (e.g., hypercapnia, hypercarbia, associated cardiac arrhythmias). In particular, patients with COPD may not be able to compensate for the absorbed CO_2 by increased ventilation; this may result in dangerously elevated levels of CO_2 in these patients, thereby necessitating the direct testing of arterial blood gases during laparoscopy or robotics in the pulmonary compromised patient. Carbon dioxide also stimulates the sympathetic nervous system, which results in an increase in heart rate, cardiac contractility, and vascular resistance. Last, CO_2 is also stored in various body compartments (e.g., viscera, bones, muscles). After prolonged laparoscopic or robotic procedures it may take hours before the patient has eliminated the extra CO_2 that has accumulated in these storage areas; again, this is more often the case and a problem in patients with pulmonary compromise (Lewis et al., 1972; Puri and Singh, 1992; Tolksdorf et al., 1992; Wolf and Stoller, 1994). Therefore, as previously noted, all patients, and in particular those with pulmonary disease, must be closely monitored after a lengthy laparoscopic or robotic procedure for possible signs or symptoms of hypercarbia; indeed, their greatest chance of compromise as a result of hypercarbia may occur after extubation in the postanesthesia recovery room.

Alternative Gases

Nitrous oxide is less irritating to the peritoneum and causes fewer acid-base changes and cardiovascular adverse effects (e.g., arrhythmias) than CO_2 (El-Minawi et al., 1981; Minoli et al., 1982; Scott and Julian, 1972; Sharp et al., 1982). However, some studies have shown that nitrous oxide insufflation reduces cardiac output and increases mean arterial pressure (MAP), heart rate, and central venous pressure (Marshall et al., 1972; Shulman and Aronson, 1984). Because nitrous oxide supports combustion, it can be used only during laparoscopic procedures that do not involve the use of electrosurgical instruments.

Helium is an inert and noncombustible insufflant. Initial studies performed in various animal models showed favorable effects on arterial partial pressure of CO_2 and pH with **no evidence of hypercarbia** (Fitzgerald et al., 1992; Leighton et al., 1993; Rademaker et al., 1995). These results were corroborated by clinical studies (Bongard et al., 1991; Fitzgerald et al., 1992; Jacobi et al., 1997; Leighton et al., 1993; Neuberger et al., 1994; Rademaker et al., 1995). **Therefore helium is particularly useful for the patient with pulmonary disease in whom hypercarbia would be poorly tolerated.** In a study from Johns Hopkins University, 10 patients at high risk for hypercarbia underwent laparoscopic renal surgery with helium insufflation. These patients were successfully managed, with only one patient developing an end-tidal CO_2 over 45 mm Hg (Makarov et al., 2007). **Likewise, if hypercarbia develops during a laparoscopic procedure with CO_2, rather than aborting the procedure or converting to an open approach, the surgeon can change the insufflant to helium and usually salvage the case** (Brackman et al., 2003). There is also evidence that the use of helium may cause a decrease in tumor cell growth and inflammatory reactions within the peritoneal cavity (Dahn et al., 2005; Jacobi et al., 1997, 1999). Helium insufflation can be used for laparoscopic procedures (e.g., cholecystectomy, appendectomy, hernia repair) performed with local and regional anesthesia in high-risk patients not only because of its favorable metabolic features but also because of its lack of peritoneal irritation and its association with decreased postoperative pain (Crabtree and Fishman, 1999). **However, laparoscopic surgeons must remember that helium may be associated with a higher risk of gas embolism because of its lower blood solubility.** When helium is going to be used, it is advised to initially obtain the pneumoperitoneum with CO_2 and then change to helium, thereby lowering the chances of a helium gas embolus. Also, helium is significantly more expensive than CO_2. Last, with use of helium a separate "yoke" (i.e., line from the gas tank to the insufflator) is needed; accordingly, surgeons must make sure that a "helium yoke" is available in the operating room or make arrangements to have one provided when performing laparoscopy on patients with severe pulmonary compromise. In practice, the use of helium may be difficult; however, argon may also be used in circumstances when hypercarbia occurs. Indeed, the gas from the argon beam coagulator can be used to maintain the pneumoperitoneum. However, with argon being an inert gas, like helium, the same precautions apply (Badger et al., 2008).

Other insufflants (e.g., room air, oxygen) have been used to establish a pneumoperitoneum in the past. However, possible serious side effects (e.g., air embolus, intra-abdominal explosion, combustion with oxygen and room air) have terminated their clinical use. Other options for insufflants include some of the other noble gases (e.g., xenon, argon, and krypton), which are inert and nonflammable; however, their widespread clinical use has not been adopted because of their high cost and poor solubility in blood.

Choice of Pneumoperitoneum Pressure

Overall, the most commonly selected pressure for performing laparoscopy or robotics is 15 mm Hg; however, studies support a pressure of 12 mm Hg as more optimal because this results in no perturbations in cardiac parameters (i.e., no change in stroke volume) versus a pressure of 15 mm Hg (Mertens zur Borg et al., 2004). Working at lower pneumoperitoneum pressures has also been found to reduce postoperative pain (Sarli et al., 2000). Using an even lower working pressure of 10 mm Hg has been shown to result in a marked reduction in oliguria (McDougall et al., 1994), and the authors routinely use a pressure of 8 mm Hg during renal surgery when using a valve-free trocar system with an Intelligent Flow System insufflator (AirSeal System, CONMED, Utica, NY). Conversely, a pressure of 20 mm Hg has been noted to produce a 22% increase in insufflant filling volume and possibly less venous bleeding during the procedure (Adams et al., 1999). However, the absolute benefit of increased insufflant filling is debatable; McDougall et al. (1994) noted that, despite the increased volume, there was only a very small increase in abdominal girth at higher pressures.

Various cardiovascular, renal, and respiratory effects seen during different intra-abdominal pressures in the supine state are summarized in Table 14.1. These physiologic parameters may be further altered (i.e., overridden or reversed) as a result of the health of the individual patient and changes in the patient's position.

TABLE 14.1

Pressure Effects: 5, 10, 20, and 40 mm Hg

EFFECTS	5 mm Hg	10 mm Hg	20 mm Hg	40 mm Hg
CARDIOVASCULAR				
Heart rate	↑	↑	↑	↓
Mean arterial pressure	↑	↑	↑	↑
Systemic vascular resistance	↑	↑	↑	↑
Venous return	→/↓	↓ ↑	↓ ↑	↓
Cardiac output	→/↓	→/↑	→/↓	↓
RENAL				
Glomerular filtration rate	→	↓	↓ ↓	↓ ↓
Urine output	→	↓	↓ ↓	↓ ↓
RESPIRATORY				
End-tidal CO_2	→	→/↑	→/↑	↑
P_{CO_2}	→	↑	↑	↑
Arterial pH	→	→/↓	↓	↓

CO_2, Carbon dioxide; P_{CO_2}, partial pressure of carbon dioxide.

Cardiovascular Effects of the Pneumoperitoneum

Venous Flow

Animal studies have shown that the effects of the pneumoperitoneum on venous return depend on atrial pressures, which, in turn, are a reflection of the hydration state of the subject (Diamant et al., 1978; Ivankovich et al., 1975; Kashtan et al., 1981). If atrial pressures are low (normal or hypovolemic state), then, during a pneumoperitoneum of up to 20 mm Hg, venous return is reduced because of increased compression of the vena cava from the pneumoperitoneum. If atrial pressures are high (hypervolemic state), the vena cava resists elevated intra-abdominal pressure and venous return is actually enhanced. However, these principles apply only to an intra-abdominal pressure of up to 20 mm Hg. By further increasing pneumoperitoneum pressures, especially to 40 mm Hg and above, capacitance vessels are collapsed, vascular resistance increases, blood flow decreases markedly, and venous return is significantly reduced. Lower extremity venous return is also reduced by elevated intra-abdominal pressures. Reduced venous blood flow in the lower extremities could facilitate deep vein thrombosis; however, this remains a rare clinical complication of laparoscopy (Jorgensen et al., 1993).

These pathophysiologic insights, gained through animal experiments, have been corroborated by clinical studies (Jorgensen et al., 1993; Kelman et al., 1972; Lee, 1975; Motew et al., 1973). As a result of these trials, intra-abdominal pressures during laparoscopy and robotics should not be allowed to exceed 20 mm Hg over extended periods (Arthur, 1970; Lee, 1975; Seed et al., 1970), and a working pressure of 10 to 12 mm Hg is recommended.

Cardiac Arrhythmias

Tachycardia and ventricular extrasystoles may be seen as results of hypercapnia (Scott and Julian, 1972). Peritoneal irritation may lead to vagal stimulation and subsequently to bradyarrhythmias (Doyle and Mark, 1989). Also, dysrhythmias can serve as clinical warning signs for the occurrence of pneumothorax, hypoxia, and gas embolism (Wolf and Stoller, 1994).

Unreliability of Central Venous Pressure Readings

As previously noted, intravenous pressures may actually rise with low intra-abdominal pressures. In addition, increasing intra-abdominal pressures may artificially elevate central venous pressure readings owing to an increase in intrathoracic pressure. Therefore the anesthetist must *not* rely on central venous pressure readings for any clinical decision making.

Respiratory Effects of the Pneumoperitoneum

Pressure-Mediated Effects

Because of increased intra-abdominal pressure, diaphragmatic motion is limited.

Pulmonary dead space remains unchanged, but functional reserve capacity decreases (Wolf and Stoller, 1994). The average peak airway pressure needed to keep up a constant tidal volume increases parallel to the increasing intra-abdominal pressure (Alexander et al., 1969; Motew et al., 1973; Wolf and Stoller, 1994).

Although usually not of great clinical importance in a healthy patient population, it is advisable to use positive end-expiratory pressure techniques when patients with lung disease undergo general anesthesia for a laparoscopic procedure (Ekman et al., 1988; Hazebroek et al., 2002; Wolf and Stoller, 1994).

Non–Pressure-Related Respiratory Effects

The head-down position, commonly used in laparoscopic and robotic procedures, has an adverse effect on respiration. It elevates the diaphragm and decreases vital capacity. It can also lead to a dislocation of the endotracheal tube that, in turn, may cause right main bronchus intubation. Although of little clinical significance in healthy patients, the head-down position may cause pulmonary edema in patients with increased left-sided heart pressures (Prentice and Martin, 1987). Also, during lengthy procedures performed with the patient in the head-down position, it is useful to limit fluid administration if possible because it will minimize facial swelling postoperatively.

Renal Effects of the Pneumoperitoneum

Increased intra-abdominal pressure was found to be associated with a significant decrease in urinary output. A number of investigators, with the oldest study dating back to 1923, have observed **oliguria** and anuria associated with an ongoing increase in intra-abdominal pressure (Harmann et al., 1982; Richards et al., 1983; Thorington and Schmidt, 1923). Decreased renal vein blood flow and direct renal parenchymal compression, rather than marked hormonal changes or ureteral compression, have been shown to be the likely reasons for the oliguric state (Chiu et al., 1994; McDougall et al., 1996). Renal cortical blood flow decreases with increasing intra-abdominal pressures, whereas renal medullary blood flow increases up to pressures of 20 mm Hg; above this level, medullary blood flow also decreases (Chiu et al., 1994).

In general, to avoid an oliguric state during a laparoscopic procedure, a pressure of 10 mm Hg or less is recommended. In addition, clinically the use of furosemide (Lasix), mannitol (12.5 to 25 g), and dopamine at 2 μg/kg/min can help overcome oliguria. With this regimen and judicious fluid administration, the patient can usually be maintained with a urine output in excess of 100 mL/h. The key is to use these pharmaceutical modalities in lieu of excessive hydration and fluid boluses (Perez et al., 2002), which may lead to significant fluid overload and edema.

Effects of the Pneumoperitoneum on Mesenteric Blood Flow and Intestinal Motility

Decreased blood flow during laparoscopic procedures was found not only in the kidney but also in mesenteric vessels and other organs (e.g., liver, pancreas, stomach, spleen, small and large intestines) (Caldwell and Ricotta, 1987; Hashikura et al., 1994; Ishizaki et al., 1993). This may rarely lead to mesenteric thrombosis with catastrophic results. This complication may take days to develop (Schorr, 1998).

Open, incisional abdominal surgery usually results in some postoperative impairment of gastric and intestinal emptying because of intestinal paralysis (physiologic ileus) (Kemen et al., 1991). Clinical observation and studies undertaken during laparoscopic and open surgical cholecystectomy have shown that laparoscopic surgery causes less significant disturbances of the gastrointestinal motility pattern, therefore resulting in no postoperative physiologic ileus or less than occurs with open surgery (Halevy et al., 1994; Sezeur et al, 1993). The exact mechanisms responsible for this difference have yet to be defined; however, it is postulated that perhaps it is related to the hypercarbia (Aneman et al., 2000). In addition, intestinal perfusion does not change significantly during prolonged pneumoperitoneum at a pressure of 15 mm Hg with CO_2 or helium (Goitein et al., 2005); however, at least in the rat model, there does seem to be an increase in bacterial translocation that is proportional to the pneumoperitoneum pressure (Sukhotnik et al., 2006).

Also, despite the increased intra-abdominal pressures associated with laparoscopy, there has been no increased incidence of gastroesophageal reflux and regurgitation in patients undergoing laparoscopic procedures (Schippers et al., 1992).

Acid-Base Metabolic Effects of Pneumoperitoneum

Animal and human studies have demonstrated that prolonged laparoscopic procedures may result in hypercarbia and respiratory acidosis (Motew et al., 1973). Because there is no increase in ventilatory dead space during laparoscopy, the resulting respiratory acidosis has been attributed to transperitoneal absorption of CO_2 during establishment and maintenance of the pneumoperitoneum (Leighton et al., 1993; Motew et al., 1973). Although the resulting mild respiratory acidosis does not adversely affect otherwise normal patients and can be corrected by increasing the minute ventilation, increased absorption of CO_2 can become dangerous in patients with COPD because of their impaired ability to release pulmonary CO_2. **To ensure proper monitoring of acid-base status, intermittent arterial blood gas sampling should be performed in patients with COPD during any laparoscopic or robotic procedure that requires more than 1 hour of CO_2 insufflation. In patients with COPD, arterial blood gas sampling should continue in the postanesthesia recovery area because after extubation these patients may be at risk of significant hypercarbia as a result of subsequent mobilization of procedurally absorbed CO_2.**

The potential for developing hypercarbia exists during transperitoneal and preperitoneal laparoscopy. CO_2 is absorbed from the peritoneal membrane during transperitoneal laparoscopy and from preperitoneal adipose and connective tissue during retroperitoneoscopy and extraperitoneoscopy (Collins, 1981). Others have also implicated the disrupted microvascular and lymphatic channels for CO_2 absorption during preperitoneal laparoscopy (Glascock et al., 1996). Several studies have demonstrated that CO_2 absorption during either transperitoneal or retroperitoneal laparoscopy increases significantly during the initial 30 to 60 minutes of the procedure and reaches a steady-state plateau thereafter (Ng et al., 1999; Wolf et al., 1995). Which one of the two approaches is associated with greater CO_2 absorption remains a debated issue. Although some studies have demonstrated greater absorption during transperitoneal laparoscopy (Giebler et al., 1997), others have demonstrated greater absorption during retroperitoneal laparoscopy using a standard Hasson cannula (Wolf et al., 1995). However, in another study, no significant clinical difference was seen (Ng et al., 1999), as long as a balloon tip–type cannula was used that tightly sealed the site of entry between the balloon and soft cuff carried on the shaft of the cannula.

Although transperitoneal and retroperitoneoscopic approaches are routinely used safely at numerous centers worldwide, vigilant perioperative anesthetic management is essential to prevent the development of potential complications related to CO_2 buildup, particularly in patients with preexisting airway and cardiovascular compromise. End-tidal CO_2 and O_2 saturation should be monitored intraoperatively with a capnometer. Furthermore, arterial blood gases are obtained during prolonged laparoscopic procedures and in patients with increased risk of developing hypercarbia (because of airway disease, renal failure, congestive heart failure, or advanced age). **A rise in end-tidal CO_2 should prompt the anesthesiologist to adjust the respiratory rate and tidal volume to enhance CO_2 elimination**. **Simultaneously, the surgeon should decrease the insufflation pressure of CO_2 or, if necessary, desufflate the abdomen until the hypercarbia has resolved.**

Hemodynamic Effects Related to Patient Position and Type of Approach

Several animal and human studies have examined hemodynamic changes resulting from different surgical positions during laparoscopy (Joris et al., 1993; Kelman et al., 1972; Williams and Murr, 1993). In the supine position, cardiac output remains unchanged or decreases when intra-abdominal pressures are less than 15 mm Hg, whereas MAP and systemic vascular resistance increase (Pearle, 1996). If pneumoperitoneum pressures are increased beyond 20 mm Hg, cardiac output is reduced because of decreasing venous return and therefore MAP decreases. Alternatively, in the head-up position, heart rate increases, MAP decreases, systemic vascular resistance increases, and cardiac output decreases. In the head-down position, heart rate drops, MAP rises, systemic vascular resistance falls, and cardiac output increases (Pearle, 1996). These results have also been shown to hold true in steep Trendelenburg position used for laparoscopic and robotic radical prostatectomy (Falabella et al., 2007). The head-down position seems to be favorable for the laparoscopy patient because of higher cardiac output caused by increased venous return.

There is some evidence that the extraperitoneal approach may be beneficial with regard to hemodynamic effects compared with transperitoneal laparoscopy. Giebler et al. (1997) demonstrated that transperitoneal laparoscopy was associated with more pronounced changes in cardiac output, pulmonary artery pressure, central venous pressure, iliac venous pressure, and inferior vena caval pressure gradient as compared with retroperitoneal laparoscopy. With regard to pelvic laparoscopy, Meininger et al. (2004) compared the effects of prolonged intraperitoneal and extraperitoneal CO_2 insufflation on hemodynamics and gas exchange. With both insufflation methods, arterial CO_2 pressure increased rapidly, reaching higher levels with extraperitoneal insufflation. Therefore patients managed with extraperitoneal insufflation required significantly higher minute ventilation. Heart rate and central venous pressure increased in both groups, whereas mean arterial blood pressure and pH decreased in both groups.

Hormonal and Metabolic Effects During Laparoscopic Surgery

As in other surgical procedures, several hormones (e.g., β-endorphin, cortisol, prolactin, epinephrine, norepinephrine, dopamine) have been noted to increase during laparoscopic surgery as a response to tissue manipulation, intraoperative trauma, and postoperative pain (Cooper et al., 1982; Lefebvre et al., 1992; Lehtinen et al., 1987). The clinical significance of increased serum arginine vasopressin levels seen in open surgery and in response to intraperitoneal insufflation during laparoscopy remains unexplained (Cochrane et al., 1981; Melville et al., 1985; Solis Herruzo et al., 1989).

Several adverse metabolic changes observed during open cholecystectomy are less pronounced with laparoscopic cholecystectomy: (1) reduced postoperative plasma glucose elevation, (2) less decrease in insulin sensitivity, and (3) reduced hepatic stress response (Glerup et al., 1995; Jakeways et al., 1994; Thorell et al., 1993).

One important feature of the catabolic response is a complex intraorgan shift of nitrogen; this reaction has been best characterized in the liver (Glerup et al., 1995). The conversion of amino acids to urea by the liver is much higher after open cholecystectomy than it is after laparoscopic cholecystectomy. Therefore the catabolic reaction of the body is decreased with a laparoscopic versus an open approach (Fischer, 1995). Indeed, in the laparoscopic patient, the reduced postoperative hepatic catabolic stress associated with reduced tissue loss of amino-nitrogen may, in some way, be responsible for the more rapid convalescence that is the hallmark of laparoscopy in general. Last, catabolic responses in the form of released cytokines and opioids, resulting from augmented neurohumoral stimuli caused by incisional tissue trauma, may also be lessened with a laparoscopic approach (Fischer, 1995).

Immunologic Effects of Laparoscopic Surgery

A number of animal and clinical studies measuring a wide spectrum of inflammatory response mediators (e.g., C-reactive protein, interleukin-6) and other markers of cellular immune functions (pan–T cells [CD3], helper T cells [CD4], suppressor cells [CD8], and natural killer cells [CD16]; delayed-type hypersensitivity skin tests; serial phytohemagglutinin-induced T-cell proliferation) have suggested that laparoscopic procedures in general result in less immunosuppression than do their open counterparts (Bolla and Tuzzato, 2003; Cristaldi et al., 1997;; Karayiannakis et al., 1997; Kloosterman et al., 1994; Nguyen et al., 1999; Trokel et al., 1994). This may also play a role in hastening convalescence after laparoscopic procedures. However, in a study by Landman et al. (2004) there was no discernible difference in immunologic parameters between patients undergoing open or transperitoneal laparoscopic radical or total nephrectomy for renal cancer. Ultimately, whether a decrease in inflammatory response mediators and improved postlaparoscopic immune status will translate into a better long-term prognosis for patients with urologic cancers remains to be determined.

Key Points: Physiologic Considerations in the Adult

- Carbon dioxide is the most commonly used insufflant because it is noncombustible and rapidly absorbed in the blood.
- Helium is potentially useful for the patient with pulmonary disease in whom hypercarbia would be poorly tolerated.
- Intra-abdominal pressures during laparoscopy should not be allowed to exceed 20 mm Hg over extended periods, and a working pressure of 10 to 12 mm Hg is recommended.

Complications and Troubleshooting in Laparoscopic and Robotic Surgery

Historically, in large series the overall incidence of laparoscopic complications in urology has been in the range of 4% and **mortality has been distinctly unusual, with a rate of 0.03% to 0.08%** (Fahlenkamp et al., 1999; Mintz, 1977; Winfield et al., 1991). More contemporary series demonstrate a complication rate in the range of 13% to 22% (Table 14.2) (Parsons et al., 2004; Permpongkosol et al., 2007; Vallancien et al., 2002), likely representative of the introduction of new, more sophisticated laparoscopic procedures and more widespread use of laparoscopy. Vascular followed by adjacent organ injuries are the most common complications (Breda et al., 2009; Permpongkosol et al., 2007). The following section covers the myriad complications that can occur with any laparoscopic or robotic procedure. Recognition, resolution, and prevention of these various problems are discussed.

TABLE 14.2

Major Complications of Transperitoneal Abdominal Surgery

TOTAL PROCEDURES	894[a] (100% ABDOMINAL)	1311[b] (84% PELVIC)
Overall complications	13.2%	22.6%
Intraoperative/postoperative	5.7%/7.5%	3.6%/19%
Death	0.2%	0%
Vascular injury	2.8%	0.5%
Bowel injury	1.1%	1.2%
Adjacent organ injury	1.1%	0.8%
Conversion rate	1.7%	1.7%

Minimizing the Incidence of Complications During the Learning Curve

Early in a surgeon's experience with laparoscopic and robotic surgery, it is wise to start with low-risk surgical candidates of normal body habitus low-risk surgical candidates of normal body habitus. In addition, it is advisable and recommended by many laparoscopic organizations, as well as by hospital credentialing boards, that the neophyte minimally invasive surgeon seek training in three arenas: (1) in-depth instructional courses, including didactic, “live-case” transmissions and “hands-on” laboratory sessions; (2) preceptor training in which the surgeon-in-training views five or more procedures being done by an already skillful laparoscopic or robotic surgeon; and (3) a mentoring experience, during which a trained laparoscopic or robotic surgeon oversees the initial procedures performed by the surgeon-in-training (Society of American Gastrointestinal and Endoscopic Surgeons, 2010). Further training can be obtained through self-teaching using videos, a laparoscopic box trainer, and virtual reality (VR) simulators. A laparoscopic box trainer is extremely helpful for developing a sense of laparoscopic proprioception and for becoming facile with laparoscopic suturing and knot tying. Data have clearly shown benefits for individuals who have taken the time to practice their laparoscopic skills using a box trainer in all areas of laparoscopy (cutting, clipping, and suturing) compared with individuals who had no such training (Derossis et al., 1998). Other options include participation in a 1-week mini-residency, which has been found to increase the likelihood that participants would perform more complex laparoscopic procedures (81% of participants) (Corica et al., 2006). In addition, VR simulators have been shown to improve the operative performance of surgical trainees with limited laparoscopic experience when compared with no training or with box-trainer training (Nagendran et al., 2013).

Aside from training in the basic psychomotor skills, neophyte minimally invasive surgeons must be educated with regard to prevention, recognition, and appropriate treatment of complications.

General Procedural Complications

Malfunction of Equipment

A successful outcome of any laparoscopic or robotic procedure depends not only on the psychomotor technical skills of the surgeon but also on a proper working knowledge of all the equipment involved in performing these procedures. To ensure undisturbed functioning of all technology, the surgeon must be supported by well-trained staff who are capable of not only quickly recognizing any equipment malfunction but also providing an immediate, adequate response to correct problems. In this regard, the Society of American Gastrointestinal Endoscopic Surgeons has issued a troubleshooting guide for video and electronic failure. For integrated operating room systems offered by most major equipment manufacturers and the da Vinci Robotic System, the surgeon and operating room staff need to receive in-depth training on the system's operation, capabilities, and limitations. In this way, equipment failure will be minimized. In addition, the contact information for the equipment vendor's troubleshooting experts and any in-house support should be readily available.

With regard to the da Vinci Robotic System, equipment malfunction is rare. In a review of 11 institutions with a total of 8240 cases reviewed, the overall incidence of malfunction was 0.4%. Of the 34 cases with malfunction, 24 cases were canceled before the procedure, 2 cases were converted to laparoscopic procedures, and 8 were converted to open surgery (Lavery et al., 2008).

Complications Related to Obtaining the Pneumoperitoneum

Complications Associated With Closed Access (Veress Needle Placement)

Preperitoneal Placement.

Preperitoneal placement of the Veress needle may preclude successful trocar placement. If not recognized early, 1 to 2 L of CO_2 may be instilled. Once this much CO_2 has been insufflated into the preperitoneal space, many signs indicative of correct intraperitoneal insufflation may be present (e.g., distention, tympanic sound on percussion), thereby misleading the surgeon until the first trocar is placed. **The first sign of preperitoneal insufflation is that there may be a steep rise in pressure with only 500 mL of CO_2; plus, if more CO_2 is instilled, unequal distention of the abdomen occurs.** If this early sign is missed, then the laparoscope or robotic camera reveals only fat after trocar placement; the intraperitoneal viscera are not seen.

The next step is to evacuate the CO_2 through the sidearm of the trocar and proceed with an open insertion technique. The initial incision can be widened, and the peritoneal surface can be grasped with a pair of Allis clamps and incised. A Hasson cannula is placed and the peritoneal cavity is insufflated.

Several steps can be taken to avoid this complication. First, if the Veress needle is preperitoneal on initial insufflation, pressures are usually higher than the maximal initial allowable pressure of 10 mm. Second, if the Veress needle is preperitoneal, it cannot be easily advanced 1 cm deeper without resistance. If one has truly entered the peritoneal cavity properly, the Veress needle should be able to be moved 0.5 to 1 cm deeper without meeting any resistance.

Vascular Injuries.

During initial placement of the Veress needle at the umbilicus, minor or major intra-abdominal blood vessels may be punctured by the 14-gauge needle. The first sign of intravascular entry is blood appearing in the hub of the needle. Aspiration results in additional blood filling the syringe. As long as the needle has not been manipulated, it can usually be withdrawn without excessive bleeding. An alternative site for Veress needle placement or open cannula insertion should be used at this point. On proper entry into the peritoneal cavity and establishment of a pneumoperitoneum, **it is important that the path of the initial Veress needle passage be traced. The prior site of the Veress needle passage should be carefully inspected at a pressure of 5 mm Hg. Any site of bleeding can be expeditiously treated by applying gentle pressure and a surgical hemostatic agent as needed.**

To prevent this problem it is important when using an umbilical approach to direct the Veress needle toward the pelvis. One technique to help prevent this problem when using an umbilical access is to pass the Veress needle after making a 12-mm incision, bluntly spreading the subcutaneous fat, and grasping and stabilizing the anterior fascia with a pair of Allis clamps. These maneuvers become especially important in children, who have less space between intra-abdominal structures and the abdominal wall.

Surgeons should also be cognizant that any hemodynamic instability associated with loss of “working space” within the abdomen during the procedure may represent an expanding “unseen” retroperitoneal hematoma from unrecognized Veress needle injury.

Prevention of vascular complications can be further achieved by using a nonumbilical site for Veress needle passage (i.e., just superior and medial to the iliac crest or subcostal in the midclavicular line), where no major vessels are placed in danger.

Visceral Injuries.

During Veress needle placement, intra-abdominal organs may be punctured. The initial signs of this complication consist of aspiration of blood, urine, or bowel contents through the Veress needle or, in the case of a solid organ, high pressures on initial insufflation.

Management consists of simply removing the Veress needle. The Veress needle may then be reintroduced at a different site, or an open Hasson technique can be used through a separate incision site. On entry into the abdomen, any bleeding site on the liver or spleen can be treated with gentle pressure, an argon beam coagulator, or the application of a surgical hemostatic agent as needed. General surgical consultation should be sought in those cases in which there is difficulty achieving hemostasis.

Bowel or bladder entry by the Veress needle needs no further treatment other than needle withdrawal. Placing a nasogastric tube and a transurethral indwelling bladder catheter to decompress the stomach and bladder, respectively, before Veress needle passage can help to prevent these problems.

Complications During Open Access (Hasson Technique).

Potential problems associated with open access are similar to, albeit less frequent than, problems associated with a closed Veress needle access. The principal risk with the open access is injury to underlying viscera while traversing the peritoneum. In a densely scarred abdomen, the bowel may be adherent to the underside of the abdominal wall and therefore may still be injured. If a bowel injury is recognized early, it can often be repaired through the same incision that was made for insertion of the Hasson cannula. Although vascular injury with this approach is distinctly rare, the surgeon must realize that even with open access this devastating complication can occur (Hanney et al., 1999).

Complications Related to Insufflation and Pneumoperitoneum

Bowel Insufflation.

If entry into the bowel is not recognized at the time of irrigation and aspiration through the Veress needle, then the surgeon may well insufflate the small or large bowel. **The first sign of this problem is asymmetric abdominal distention followed by flatus and insufflation of only a small amount of CO_2 (<2 L) before high pressures are reached.**

If this complication is suspected, then the insufflation line should be disconnected; the outflow of gas will immediately confirm bowel entry. The needle can be withdrawn, and open access cannula placement should be done at a different abdominal site. Prevention of this problem is ensured if one properly performs the aspiration, irrigation, and aspiration tests recommended for safe Veress needle placement and if one avoids sites of prior surgery. Alternatively, initial use of open access technique should avoid this complication.

Gas Embolism.

CO_2 has favorable solubility in blood, as opposed to air, helium, or nitrous oxide; however, use of CO_2 may still result in a gas embolus. The most common cause of CO_2 embolism is puncture of a blood vessel or organ with the Veress needle, followed by insufflation; this can occur only when the surgeon has ignored the previously described tests for proper entry into the peritoneal cavity. The first sign of intravascular insufflation is acute cardiovascular collapse. Other signs include dysrhythmias, tachycardia, cyanosis, and pulmonary edema. **The diagnosis is usually made by the anesthesiologist based on an abrupt increase of end-tidal CO_2 accompanied by a sudden decline in oxygen saturation and then a marked decrease in end-tidal CO_2** (Loris, 1994). Sometimes, a “millwheel” precordial murmur can be auscultated (Keith et al., 1974). In addition, the anesthesiologist may notice foaming of a blood sample, if drawn, as a result of the presence of insufflated CO_2.

The treatment is immediate cessation of insufflation and prompt desufflation of the peritoneal cavity. The patient, if at all possible, is turned to a left lateral decubitus (i.e., right side up), head-down position in hopes of minimizing right ventricular outflow problems and forcing the air embolus to rise into the apex of the right ventricle. The patient is hyperventilated with 100% oxygen. Advancement of a central venous line into the right side of the heart with subsequent attempts to aspirate gas may rarely be helpful. The use of hyperbaric oxygen and cardiopulmonary bypass has also been reported (Abdel-Meguid and Gomella, 1996; Diakun, 1991; McGrath et al., 1989).

This devastating complication can be precluded by meticulous attention to Veress needle and initial trocar placement and performance of each of the recommended tests for intraperitoneal entry. Insufflation should never be initiated if the surgeon has even the slightest doubt about correct positioning of the Veress needle; instead, the surgeon should withdraw the Veress needle and pass it at an alternate site or should immediately proceed with open access.

Barotrauma.

Prolonged elevated pressures (>15 mm Hg) may result in barotrauma (Abdel-Meguid and Gomella, 1996; Diakun, 1991; McGrath et al., 1989). Prolonged high pressures may be caused by insufficient and infrequent monitoring of CO_2 pressure, malfunction of the insufflator, or additional pressures produced by auxiliary devices (e.g., argon beam coagulator, CO_2-cooled laser). Furthermore, barotrauma may be caused by ventilation techniques using positive end-expiratory pressure, resulting in rupture of a pulmonary bleb or bulla.

The initial sign of barotrauma may be hypotension caused by decreased cardiac output, secondary to an acute drop in venous return caused by compression of the vena cava. Also, a pneumothorax or pneumomediastinum may develop because of the high ventilation pressures. In addition, increased intra-abdominal pressures may exacerbate a hiatal hernia.

The anesthesiologist, who will notice an increase in ventilation pressures, usually alerts the surgeon to excessive intra-abdominal pressure. The surgeon should desufflate the abdomen and, once the hemodynamic changes have been reversed, reinitiate the pneumoperitoneum at 10 mm Hg. Any malfunctioning insufflator should be replaced. Also, if an argon beam coagulator or a CO_2-cooled laser device is used, the sidearm on one port should be left open to allow excess high-pressure gas to escape while the device is being activated.

Barotrauma secondary to insufflator malfunction can be avoided by routinely troubleshooting the insufflator before every case.

Subcutaneous Emphysema.

Subcutaneous emphysema develops as a result of improper placement of the Veress needle or, more commonly, to leakage of CO_2 around ports. The latter situation occurs when a secure seal around the Hasson cannula is not obtained, port site incisions are too large, the procedure is particularly lengthy, or high intra-abdominal pressures are used. The pathognomonic sign is crepitus over the abdomen and thorax; in male patients, a pneumoscrotum may also develop.

If the problem is caused by improper placement of the Veress needle, then withdrawal of the Veress needle and use of the open technique are recommended. If the problem develops intraoperatively, the surgeon should check for gas leakage around a port site, including the Hasson cannula if the open technique was used. If leakage is found, the surgeon can either place a purse-string suture around the port or, preferably, change the trocar to a larger size or switch to a balloon trocar, which creates a tight seal between the intra-abdominal balloon and outer cuff. Also, the surgeon should consider reducing the insufflation pressure. This complication is eminently avoidable if the surgeon adheres to all the diagnostic tests for proper Veress needle placement and ensures all port site incisions are carefully tapered to the size of the port to be placed. In this regard, it is important to place each port so that it is pointing toward the surgical field to avoid the continued forceful redirection of the port during the procedure that results in widening of the tissue tract around the port and subsequent escape of CO_2 into the surrounding subcutaneous tissues.

Several studies have demonstrated that the incidence of subcutaneous emphysema is higher during retroperitoneal laparoscopy than during transperitoneal laparoscopy, albeit without any clinically significant sequelae (Wolf et al., 1995; Zhao et al., 2008). In any event, the risk of surgical emphysema and other CO_2-related sequelae during retroperitoneoscopic and extraperitoneoscopic surgery can be effectively minimized by working at a lower pressure (i.e., 12 mm Hg vs. 15 mm Hg) (Rassweiler et al., 1998a) and using a balloon trocar to seal the initial entry site (Gill, 1998; Ng et al., 1999).

Pneumomediastinum, Pneumothorax, and Pneumopericardium.

Gas leaking along major blood vessels through congenital defects or secondary enlargement of openings in the diaphragm may lead to pneumomediastinum, pneumopericardium, or pneumothorax (Abreu et al., 2004; Kalhan et al., 1990; Pascual et al., 1990; See et al., 1993; Zhao et al., 2008). Although a pneumomediastinum is usually not associated with specific clinical symptoms, a pneumopericardium may result in impaired cardiac function. The incidence of the pneumopericardium is estimated to be 0.8% (Abreu et al., 2004). The diagnosis is usually made on a chest radiograph taken in the recovery room, except in rare instances when cardiac impairment occurs during the procedure. If there is sudden cardiac decompensation during a procedure, the same maneuvers should be undertaken as described for treatment of a suspected gas embolism, including interruption of the procedure and desufflation of the abdomen. If there is a strong suspicion of pericardial tamponade, pericardiocentesis is indicated.

A pneumothorax may be associated with pneumomediastinum, barotrauma, or direct puncture of the pleural space with a trocar (Doctor and Hussain, 1973; Kalhan et al., 1990; Pascual et al., 1990). The incidence of this complication has been found to be 1.6% to 4.0% (Abreu et al., 2004; Zhao et al., 2008). Like subcutaneous emphysema, the incidence of pneumothorax is more common in retroperitoneal procedures (Zhao et al., 2008). The earliest signs of this problem may be the development of subcutaneous emphysema, especially in the neck and chest area. More ominous signs, such as hypotension and decreased breath sounds with an increase in ventilatory pressure, are indicative of a *tension* pneumothorax. Although a chest radiograph will confirm the diagnosis, the development of pulmonary collapse with loss of breath sounds on one side mandates immediate decompression of the chest by passage of a 16-gauge needle into the second or third intercostal space in the midclavicular line followed by tube thoracostomy, if a tension pneumothorax is suspected (See et al., 1993).

Prevention of these problems is similar to the means to avoid subcutaneous emphysema: the surgeon must keep the intra-abdominal pressure preferably at 12 mm Hg, make sure all port site incisions are tight around the laparoscopic cannulae, and make sure all cannulae are well seated in the peritoneal cavity. In addition, all trocars must remain below the 12th rib. While dissecting in the upper quadrants of the abdomen, especially during laparoscopic ablative renal surgery, the surgeon should be aware of the anatomic relationships of the kidneys, adrenal glands, and great vessels to the diaphragm to avoid direct injury.

Complications Related to Initial “Blind” Placement of the First Trocar After Obtaining a Veress Needle Pneumoperitoneum

With the advent of nonbladed trocars (several of which also have clear tips for direct visualization of individual abdominal wall layers during port placement), the likelihood of catastrophic injuries to vital structures has been markedly reduced (Thomas et al., 2003).

Injury to Gastrointestinal Organs.

Perforation of the small or large intestine during passage of the primary port is the most common cause of trocar-induced injury of gastrointestinal organs. Other organs (e.g., stomach) are affected much less frequently. Given the lateral positioning of the spleen and liver, injury of these organs with the passage of the primary trocar is distinctly unusual. The first sign that surgical tools have entered the bowel depends on whether the injury is through one wall or both walls of the bowel. In the former instance, as soon as the laparoscope is introduced, the surgeon sees the mucosal folds of the interior of the bowel. However, with a through-and-through injury the diagnosis is not made until the first secondary trocar is passed; **at that time the surgeon should routinely pass the laparoscope through the secondary port to inspect the puncture site of the initial port.** The trocar will be seen passing completely through both walls of the bowel. If the surgeon fails to perform this maneuver routinely, this injury will not be noted until the end of the case when the trocars are being removed, thereby resulting in a broader injury and a prolonged time of intraperitoneal contamination. A missed bowel injury of this nature leads to peritonitis when diagnosed intraoperatively and possible death when discovered only in the postoperative period.

In the case of a one-wall injury of the bowel, the surgeon can elect to leave the trocar in place and pass a second trocar in another location using an open-access technique. On inspection of the abdomen, the site of injury to the bowel will be immediately apparent because the initial trocar will still be residing in the bowel. At this time, the surgeon may elect to open and repair the bowel or, if skilled in laparoscopy, may place two more ports and proceed to close the bowel using laparoscopic suturing or stapling techniques. An intraoperative consultation with a general surgeon should be obtained regardless of whether the urologist performs the repair because involvement of the general surgeon at the time of the acute event facilitates subsequent care should further complications arise while ensuring the best possible repair of the injury at the time of the acute event.

When the injury to the bowel is a through-and-through injury, it can be repaired similarly with an open or laparoscopic approach. In either case, the abdomen should be irrigated with 4 to 5 L of saline containing an antibiotic solution, and the patient must be placed on broad-spectrum antibiotic coverage.

Perforation of the stomach is distinctly rare, and the management of this complication is the same as for injury to the bowel, with primary closure and general surgery consultation. In addition, when the stomach is distended, a nasogastric or orogastric tube should be placed to decompress the stomach and facilitate further trocar insertion.

Injury to Intra-abdominal Vessels.

Major vascular injury is a rare but serious complication, occurring in 0.11% to 2% of cases (Geers and Holden, 1996; Hanney et al., 1995; Lin and Grow, 1999;

Parsons et al., 2004; Usal et al., 1998; Vallancien et al., 2002). It is far more common in procedures related to the retroperitoneum as opposed to pelvic laparoscopy. The aorta and common iliac arteries are most frequently involved. The inferior vena cava is less affected because of its lateral location in relation to the aorta; likewise, the common iliac vein is rarely involved, given its posterior position in relation to the common iliac artery. Rarely, in a patient with adhesions or prior surgery, intestinal mesenteric vessels servicing a “fixed” loop of bowel may be injured. In addition, the epigastric vessels are at risk for injury during trocar placement.

The first sign of a major vascular complication is the onset of sudden hypotension and associated tachycardia. If the trocar has not been moved, then, as the obturator is withdrawn, the diagnosis is made immediately based on whether there is pulsatile (arterial) or nonpulsatile (venous) profuse bleeding from the trocar sheath. If the trocar has been displaced from the injured vessel, then, depending on the vessel injured, when the laparoscope is introduced the surgeon will see blood rapidly accumulating in the abdominal cavity, a mesenteric hematoma, blood dripping from the trocar entry site, or, rarely, blood that preferentially accumulates retroperitoneally, in which case the space within the peritoneal cavity will appear to be markedly reduced and actively decreasing because of the expanding retroperitoneal hematoma.

The response to injury to a major arterial or venous structure must be rapid. A vascular or trauma surgeon should be called to the room. If blood is coming through the trocar, then the trocar should be closed and left in place. An emergency laparotomy is performed, and the trocar is followed to its point of entry into the vessel. The injured vessel should be controlled proximal and distal to the site of trocar injury with vessel loops or bulldog clamps, or alternatively a Satinsky clamp can be placed to isolate the area of injury so that as the trocar is withdrawn the wound can be controlled and repaired quickly. If the injury is discovered at the time of passage of the laparoscope (i.e., the trocar is no longer residing in the vessel), then swinging the sheath and laparoscope up to the underside of the abdominal wall and an immediate cutdown on top of the laparoscope and sheath provide for a rapid and safe laparotomy. Alternatively in this situation, the procedure can be converted to a hand-assist approach and the surgeon can then use the intra-abdominal hand to control the bleeding vessel.

The best way to handle this complication is to avoid it completely. In this regard, knowledge of the exact location and possible anatomic variations of major intra-abdominal blood vessels is mandatory. The preoperative computed tomography (CT) scan should be reviewed before operating to look for vena caval or other abnormalities of the great vessels. Because of limited intraperitoneal space, special care must be given to trocar placement in children and very thin adults. Several maneuvers can be used to help prevent vascular injury. These include ensuring that all the safety signs of passage of a Veress needle are present before proceeding with trocar passage, obtaining an adequate pneumoperitoneum before trocar passage (intra-abdominal pressure may be raised to 20 mm Hg temporarily for placement of the primary trocar), passing the initial trocar under direct endoscopic control (i.e., optical trocar), using blunt nonbladed trocars, and avoiding initial trocar passage through an abdominal scar.

Furthermore, it is helpful to consider having a "hemorrhage" tray available in the operating room at all times (Box 14.3). **This laparoscopic tray should contain a Satinsky clamp, a 10-mm suction tip for large clot evacuation, an Endo Stitch device with 4-0 Vicryl suture, a Lapra-Ty clip applier and a rack of Lapra-Ty clips (six clips per rack), two laparoscopic needle holders, and 4-0 vascular suture.** With this tray available, some injuries to major venous structures can be successfully resolved laparoscopically.

Box 14.3

Contents of Hemorrhage Tray for Laparoscopic Surgery

Laparoscopic Satinsky clamp
10-mm suction-irrigation tip
Endo Stitch device with 4-0 absorbable suture
Lapra-Ty clip applier and a packet of Lapra-Ty clips
6-inch length of 4-0 vascular suture on an SH needle with a Lapra-Ty clip preplaced on the end
Two laparoscopic needle drivers
Topical hemostatic agent of choice

SH, Small half.

Injury to the Urinary Tract.

Urinary tract injuries during laparoscopy are most commonly associated with trocar passage, specifically injury to the bladder at the time of initial trocar placement. The incidence varies widely in the gynecologic literature, ranging from 0.02% to 8.3% (Lin and Grow, 1999; Ostrzenski and Ostrzenska, 1998; Soong et al., 2007). Chances of this problem occurring have been greatly reduced by the introduction of blunt trocars.

The initial sign of this problem is pneumaturia or gross hematuria. The diagnosis can be confirmed by retrograde intravesical instillation of indigo carmine diluted with saline; this allows the surgeon to rapidly identify the cystotomy site. The injury can be repaired laparoscopically with laparoscopic suturing techniques; however, extensive defects may require open surgical repair (Ostrzenski and Ostrzenska, 1998). These injuries should always be closed and not left to heal on their own with prolonged Foley catheter drainage.

Prevention of this problem is simple. Preoperative placement of a urethral catheter to drain the bladder is recommended for all major laparoscopic urologic cases. Not only does it largely preclude bladder injury, but it also provides the necessary means for monitoring urine output during major laparoscopic procedures.

Complications Related to Placement of Secondary Trocars

Bleeding at the Sheath Site.

Blood dripping from the port entry site and onto the underlying abdominal viscera is the first sign of an injured abdominal wall vessel. The exact site of hemorrhage is determined by cantilevering the trocar into each of the four quadrants and noting which position of the trocar tamponades the bleeding.

Definitive therapy for this problem can be undertaken in one of three ways. The simplest method, albeit the most costly, is the insertion of curved electrosurgical scissors or forceps through another port, which can then be articulated up into the port site to coagulate the bleeding.

The least expensive method is to suture the area of hemorrhage. This can be accomplished by inserting a straight Keith needle with a 0-0 absorbable suture from the outside of the abdomen at one side of the affected quadrant and then grasping the needle with laparoscopic forceps and pushing it back out of the abdomen at the opposite side of the affected quadrant until it can be recovered on the surface of the abdomen (Fig. 14.29). This broad suture is then tied over a gauze 4- × 4-inch bolster on the abdominal surface; the port can be used throughout the procedure. Alternatively, various port closure devices, in particular the Carter-Thomason device, may be used to similarly pass a suture to control the bleeding (Ortega, 1996). Ultimately, at the end of the procedure a device of this type should be used to definitively close the port site and occlude the injured vessel, no matter which of the aforementioned techniques is used.

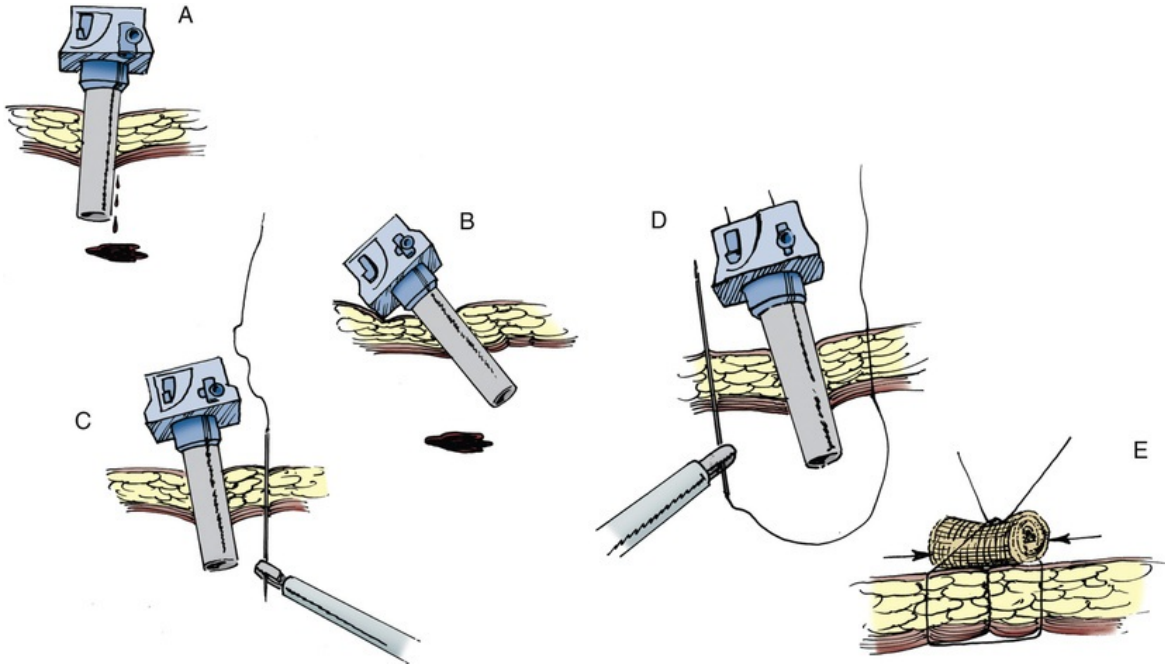

FIG. 14.29 (A) Bleeding at the cannula site. (B) Cannula can be cantilevered into each of the four different quadrants to identify the source of bleeding. (C and D) Straight Keith needle may be used to traverse the site of bleeding. (E) Suture is tied down over a gauze bolster. (From Clayman RV, McDougall EM, editors: *Laparoscopic urology,* St. Louis, 1993, Quality Medical Publishing.)

This problem can often be avoided by routinely transilluminating the abdominal wall, especially in the thin patient, before trocar placement so that large surface vessels and overlying peritoneal vessels can be avoided and to help identify the area of the inferior epigastric vessels. In addition, the routine spreading of the subcutaneous tissues at the proposed port site with a blunt clamp (e.g., Kelly clamp) may be helpful, and the use of only **blunt trocars has been shown to reduce the chance of vascular wall injury significantly** (Bhoyrul et al., 2000). In particular, a fivefold decrease in epigastric vessel injury has been demonstrated with blunt trocars (reduced incidence from 0.83% to 0.16%) (Hashizume and Sugimachi, 1997; Thomas et al., 2003). The incidence of any abdominal wall bleeding has also been shown to be dramatically reduced (3% vs. 9%) with blunt versus bladed trocars (Antoniou et al., 2013). Placing trocars either in the midline or at least 6 cm lateral to the midline has also been shown to reduce the risk of epigastric vessel injury (Hashizume and Sugimachi, 1997).

Trocar Position–Related Problems.

Three potential problems may occur when the secondary trocars are not properly positioned: "crossing swords," "striking handles," and "rollover." The problem of crossing swords is caused by the trocars being placed too close to one another; as a result, the intra-abdominal portions of two trocars cross each other so that the two trocars cannot be easily used to deliver instruments to the same surgical site. Similarly, the problem of striking handles is also caused by trocars being placed too close to one another. As a result, the upper portions of the trocars strike one another on the abdominal surface, again precluding delivery of instruments to a specific surgical site. Rollover is a variant of the crossing swords problem, but it occurs between the laparoscope and an instrument. Instead of running parallel to the surgical site, the primary cannula holding the laparoscope and one of the instrument-holding secondary ports are pointed toward each other. Consequently, as the instrument is advanced toward the surgical site, it strikes and is deflected by the larger laparoscope, thereby rolling over the laparoscope and therefore suddenly moving out of the field of view.

By definition, these problems are more likely to occur during LESS. Because the ports are purposely placed in close proximity to one another, the surgeon must use advanced techniques or special equipment to overcome these pitfalls. This special equipment may include articulating instrumentation, instruments with different shaft lengths, and a low-profile 5-mm laparoscope.

When the da Vinci Robotic System is used, the ports should be placed at least 8 to 10 cm away from one another to avoid robotic arm collision—the robotic equivalent of striking handles. This can sometimes be challenging in thin patients with limited abdominal wall space.

Usually these problems are a minor annoyance, and the surgeon and assistant need to experience the problem only once to adjust for it. To compensate for the problem of striking handles, if it should occur, the sheaths can be withdrawn a bit from the abdomen, thereby increasing the space between the handles of the instruments. The problems of crossing swords and rollover can be remedied by moving the handles of the crossing trocars closer to each other, thereby moving the tips of the trocars farther apart. When this is done to correct a rollover, the surgical site may be displaced into one corner of the monitor; however, the desired delivery of the instrument to the surgical site can then be accomplished. A 30-degree laparoscopic lens can usually allow the laparoscope to be placed parallel to the instrument it is rolling over and then rotated to maintain the operative site image and eliminate the rollover.

The best way to handle these situations is to properly place and direct each trocar at the beginning of the case, to avoid encountering these problems. For some procedures, such as pyeloplasty, this may be accomplished by placing all the trocars on the same line (i.e., midline) so that they are all working parallel to one another, whereas for procedures such as nephrectomy the goal is to place the trocars so that they surround the surgical site, forming a diamond pattern within which the kidney lies. Regardless, each trocar must be inserted so that it points to the pathology; this precludes the problem of having to redirect the trocar throughout the case, adding to surgeon fatigue and unnecessary trauma to the peritoneum and abdominal wall musculature. **Last, if trocar interactions become particularly vexing during a procedure, the surgeon should not hesitate to place an additional 5-mm trocar in a more conducive site to eliminate the problem.**

Complications Related to General Anesthesia Unique to Laparoscopy

Cardiac Arrhythmias and Cardiac Arrest.

Cardiac arrhythmias can be frequently seen during anesthesia in laparoscopic procedures; the most common is sinus tachycardia. Bradyarrhythmias (e.g., atrioventricular dissociation, nodal rhythm, sinus bradycardia) may develop independently or in combination with tachycardia during the same procedure (Myles, 1991). Conditions in laparoscopy leading to development of arrhythmias include CO_2 insufflation; hypercapnia; Trendelenburg position; anesthetic drugs (especially halothane in combination with spontaneous ventilation); and gas embolism (Harris et al., 1984; Myles, 1991). In rare cases, asystolic cardiac arrest and cardiovascular collapse may develop (Shifren et al., 1992).

The role of the anesthesiologist throughout the laparoscopic procedure is paramount. Continuous monitoring of cardiovascular parameters (electrocardiogram, arterial blood pressure) and pulmonary parameters (capnometry, in-line oxygen, airway pressures and tidal volume, frequent arterial blood gas analyses when indicated) is essential. Invasive cardiac monitoring should be instituted as appropriate in patients with heart disease or in high-risk patients (i.e., American Society of Anesthesiologists type 3 or 4) when prolonged and complicated laparoscopic procedures are expected.

Because hypercarbia is one of the most common underlying causes of cardiac arrhythmias, it is essential to monitor and control this problem. Overall, hypercapnia can be corrected rapidly by adjustment of ventilatory rate and tidal volume, use of positive end-expiratory pressure as needed, and reduction of intra-abdominal pressure to 10 mm Hg. The surgeon can also desufflate the abdomen for 5 to 10 minutes to allow the anesthesiologist to “catch up” and correct the hypercarbia; pneumoperitoneum can then be reinitiated at a lower pressure.

In rare cases, if the hypercarbia cannot be controlled by these maneuvers, helium should be substituted for CO_2 as the insufflant. For patients with preoperatively known severe pulmonary compromise, it is prudent to have a tank of helium and the proper helium yoke available in the operating room so that the insufflant can be easily switched. Alternatively, argon gas can be used in the acute situation because it is readily available in many operating rooms because of the argon beam coagulator (Badger et al., 2008).

In the event of cardiac arrest, the surgeon should immediately desufflate the abdomen and provide cardiac massage (compressions) while the anesthesiologist administers 100% oxygen and appropriate drug therapy. If a CO_2 embolus is suspected, additional maneuvers, such as immediately turning the patient to a left lateral decubitus, head-down position and possibly attempting to aspirate the embolus, may be performed.

Changes in Blood Pressure.

Hypertension may be caused by inadequate general anesthesia, elevated intra-abdominal pressures, or hypercarbia. Hypotension may be the result of hypoxia, pneumothorax, pneumomediastinum, gas embolus, or hemorrhage (Abdel-Meguid and Gomella, 1996).

In the event of a marked change in blood pressure, one of the aforementioned conditions must be ruled out. The initial response of the surgeon, provided that there is neither active bleeding nor evidence of retroperitoneal hemorrhage, should be to desufflate the abdomen. In addition, therapy specific to an underlying cause should be enacted.

Aspiration of Gastric Contents.

Aspiration of gastric contents may occur more frequently in patients with a hiatal hernia, significant obesity, diabetes with a history of gastroparesis, or any form of gastric outlet obstruction (Hanley, 1992). The combination of elevated intra-abdominal pressures from the pneumoperitoneum, morbid obesity, and use of the Trendelenburg position increases the likelihood of this complication (Abdel-Meguid and Gomella, 1996).

To prevent this problem in high-risk patients, oral or intravenous administration of 10 mg of metoclopramide is recommended. This medication may decrease the incidence of aspiration by increasing the tone of the lower esophageal sphincter. In addition, in patients with known gastroesophageal reflux, H_2 blockers reduce gastric acidity and attendant morbidity if aspiration of gastric contents should occur (Abdel-Meguid and Gomella, 1996; Hanley, 1992). Also, in patients with known gastroesophageal reflux or other predisposing factors for gastric aspiration, a cuffed endotracheal tube should always be placed. Last, among these high-risk patients, administration of atropine should be avoided because it decreases the tone of the lower esophageal sphincter (Duffey, 1979).

Hypothermia.

The patient's core temperature may drop during prolonged laparoscopic procedures, especially if there is leakage of insufflant around the port sites. The CO_2 that is used is typically neither warm nor humidified. The resulting decrease in temperature may be 0.3°C for each 50 L of CO_2 insufflated (Ott, 1991b). The ambient operating room temperature may exacerbate this effect.

The clinical effects of hypothermia are well described. Core body temperatures around 35°C may result in (1) increased bleeding tendency caused by impaired platelet function, reduced activity of coagulation factors, and enhanced fibrinolysis; (2) increased adrenergic response with vasoconstriction and increased arterial blood pressure; (3) prolonged recovery time as a result of increased blood gas solubility; (4) twofold to threefold increase in the incidence of early postoperative myocardial ischemia in high-risk patients; and (5) impaired wound healing and increased susceptibility to wound infections (Rosenberg and Frank, 1999).

In general there are no specific signs that can be appreciated intraoperatively except for cardiac arrhythmias. In particular, atrial fibrillation may occur in extreme cases of hypothermia (body core temperature of approximately 30°C).

In almost all cases, hypothermia can be avoided. Adjuncts to support the patient's body temperature include intravenous fluid warming, active warming by forced-air systems, circulating warm-water mattresses, and radiant heaters (Rosenberg and Frank, 1999). In addition, warming and humidifying CO_2 to physiologic levels, especially when a prolonged laparoscopic procedure is anticipated, is helpful (Ott, 1991a). However, warming the insufflant alone should be avoided because this causes a drying of the intraperitoneal tissues and has been associated with increased postoperative patient discomfort (Slim et al., 1999).

Complications Related to the Surgical Procedure

Bowel Injury: Electrosurgical.

Electrosurgically induced thermal injury may occur through of one of four mechanisms: inappropriate direct activation; coupling to another instrument; capacitive coupling; and insulation failure.

Active electrode trauma by unintended activation causes direct bowel or other organ injury and may occur when the electrosurgical instrument is left unobserved within the peritoneal cavity, when it is out of the camera's view, or when someone other than the primary surgeon carries out electrode activation. Furthermore, active electrode trauma may be seen when coagulation extends beyond the intended site (thermal spread) and reaches other adjacent structures (e.g., bowel, blood vessels, ureter). This is more commonly seen when high electrocoagulation settings (i.e., >30 watts) are used.

Direct coupling may occur when the active electrosurgical instrument touches another instrument that is in direct contact with other tissue (e.g., bowel). If this happens outside the field of view of the laparoscope or robotic camera, it may remain unnoticed by the surgical team.

Injury caused by capacitive coupling occurs when the surrounding charge, which is intrinsic to all activated monopolar electrodes, is not allowed to conduct back to and disperse through the abdominal wall (Munro, 1997; Zucker et al., 1995). This condition may develop when a metal cannula is anchored to the skin with a nonconductive plastic grip, which, as previously noted, should never be done (Fig. 14.30). As a result, the electrical field, which builds up around the activated electrosurgical instrument and is conducted to the metal trocar through which it has been placed, cannot then be conducted to the abdominal wall because the plastic retainer acts as an insulator. This may lead to a high power density along the portion of the metal cannula that is inside the abdomen. The electrical charge built up on the cannula can then travel to other tissues in contact with the cannula. Similarly, capacitive coupling may constitute a risk when electrosurgical probes are used through operating laparoscopes, which are, in turn, inserted through plastic sheaths. The metal shaft of the laparoscope then becomes a repository for electrical current and may discharge this energy to any tissue in contact with the laparoscope. The risk of this complication is also increased when older generators with high-voltage output and/or electrodes with thicker diameters are used, especially in coagulation rather than cutting mode (Munro, 1997).

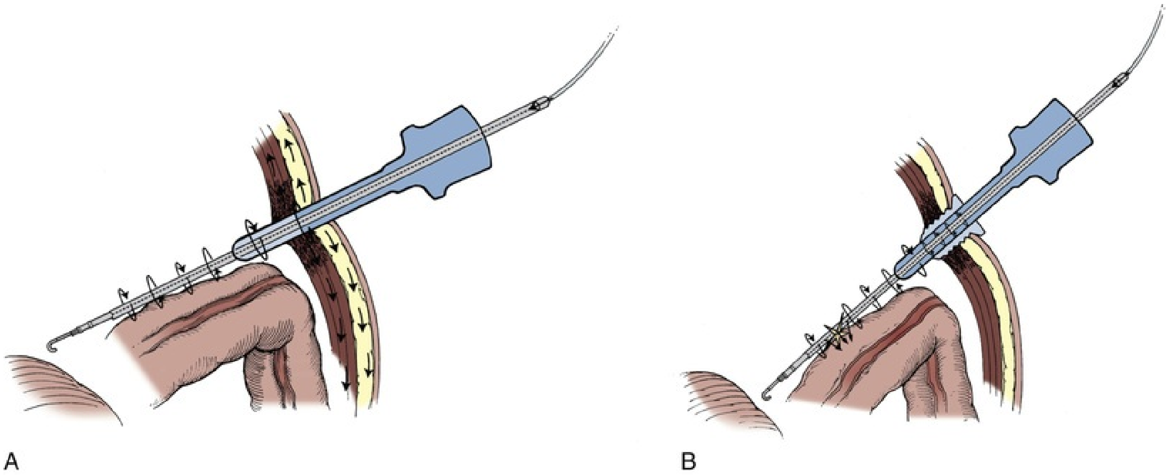

FIG. 14.30 Capacitive coupling. (A) Charge surrounding the activated monopolar electrode is conducted back to the all-metal cannula and dispersed by the abdominal wall. (B) The electrosurgical instrument is being used through a metal cannula that has been anchored to the skin with a nonconductive plastic grip; accordingly, the electrical field cannot be conducted to the abdominal wall because the plastic retainer acts as an insulator; a stronger electrical charge is thus conducted to any other tissue in contact with the cannula.

Last, insulation breakdown may allow current to escape along the shaft of the instrument, thereby harming tissues that are otherwise outside the field of view of the laparoscope. Insulation breakdown along the shaft of the instrument may be a result of repeated use, resterilization, or mechanical damage to the instrument during repeated insertion through a trocar. In this situation, the small break in insulation results in an area of very high power density that then discharges to the nearest soft tissue.

Intraoperatively, thermal injuries of the bowel may manifest as whitish spots on the serosal lining. In severe cases, the muscularis mucosae or the intestinal lumen may be seen. However, in many patients, thermal injury to the bowel is not recognized at the time of the procedure. **Postoperatively, the patient with unrecognized bowel trauma may not develop fever, nausea, or signs of peritonitis for many days because the full extent of bowel necrosis may take up to 18 days to fully develop** (Abdel-Meguid and Gomella, 1996). **Therefore the problem may not become evident until the patient has actually been discharged from hospital.**

Accordingly, bowel injury must be ruled out for any patient who develops a fever beyond postoperative day 1 or who complains of increasing abdominal discomfort. Although many patients may have the typical signs of fever, abdominal pain, ileus, and nausea and vomiting, this is not always the case. Instead many **patients may have low-grade temperature, leukopenia, and persistent and relatively extreme pain at the trocar site closest to the bowel injury** (Bishoff et al., 1999). Alternatively, laboratory values may be remarkable for leukocytosis with an associated left shift (i.e., increased percentage of neutrophils). In some patients, this occurs in the face of a normal or even low leukocyte count, making the left shift a more reliable sign than the absolute white cell count. Abdominal radiographs are notoriously inaccurate because the CO_2 from the laparoscopy may remain as free air for up to 9 days after the procedure; however, an ileus pattern is usually present. A more sensitive test is an abdominal CT scan with oral contrast accompanied by delayed films.

Minor postoperative thermal injuries of the bowel discovered late in the postoperative period (i.e., more than 5 to 7 days postoperatively) may be managed conservatively, aided by administration of antibiotics and an elemental diet. Indeed, a closed fistula may develop that will heal with this approach. However, if the patient does not respond rapidly or develops worsening peritonitis, open surgical exploration is mandatory. Thermal injury caused by monopolar cautery often results in tissue damage that extends beyond the visible area of necrosis. With this in mind, the surgeon should perform a bowel resection with a safety margin of 6 cm on either side before completing an end-to-end anastomosis (Abdel-Meguid and Gomella, 1996).

Thermal injury caused by bipolar electrosurgery is more confined to the visible area of damage. These injuries occur only as a result of direct firing of the instrument on the bowel. If the injury is small, it can be managed by simple excision of the defect and closure of the bowel wall. Bipolar injuries that involve more than half the circumference of the bowel should be treated by excision of the affected segment of the bowel followed by end-to-end anastomosis (Abdel-Meguid and Gomella, 1996).

The goal of every laparoscopic surgeon is to never experience a thermal complication. The surgeon can take several steps to lessen the risk. First, electrosurgical instruments must be carefully inspected before use for any “breaks” in the insulation; if these are found, the instrument must be sent for recoating. Second, electrosurgical instruments should never be left untended within the abdomen; when not in use they must be removed from the abdomen. Third, *only* the primary surgeon should control electrode activation. Fourth, isolation of the area to be cauterized from the surrounding tissues (vessels, nerves, ureter), as well as use of bipolar electrocautery, reduces the risk of thermal spread and injury to other tissues. Fifth, the electrosurgical device should never be activated unless the entire extent of the metal portion of the instrument is in view. This includes not only the active tip of the instrument but also any exposed, uncoated metal joints that may lie just behind the tip of the instrument. In this manner inadvertent direct injury to adjacent tissue and direct coupling to another instrument can be avoided. Sixth, problems of capacitive coupling can be precluded by not creating a situation in which a mixture of conducting and nonconducting elements is used by the surgeon (e.g., metal trocars combined with plastic retainers). In addition, use of modern generators and small-diameter electrodes can significantly decrease the risk of capacitive coupling (Munro, 1997), as can the use of blended or pure cutting current. The high voltages needed for pure coagulation current pose the greatest threat for electrosurgical injury, especially through the mechanism of capacitive coupling and insulation failure. Last, an active electrode monitoring system (Encision, Boulder, CO) is extremely helpful. With this system, any sudden break in the insulation of the electrosurgical instrument (e.g., with scissors or hook electrode) results in immediate shutdown of the electrosurgical current, thereby precluding an electrosurgical injury.

Bowel Injury: Mechanical.

Inadvertent mechanical damage can be caused by a wide variety of sharp and blunt instruments (e.g., laparoscopic graspers, scissors, retractors). This type of injury is more visible to the surgeon and is usually discovered intraoperatively or at the end of the procedure. Direct visual identification during the procedure allows the surgeon to repair the injury laparoscopically, even though the patient has not had a formal bowel preparation. Given its localized nature, bowel resection is rarely necessary. The abdomen should be irrigated copiously at the end of the procedure with 4 to 5 L of an antibiotic-containing solution.

If mechanical bowel injury is missed during the procedure, then postoperative symptoms typically develop much earlier than with an electrosurgical injury. Fever, nausea, ileus, and peritonitis develop in the very early postoperative period, and the diagnosis is confirmed by an abdominal CT scan with oral contrast. This type of injury should be managed with immediate return to the operating room to correct the problem by local excision or resection of bowel with subsequent end-to-end anastomosis and copious irrigation of the abdomen.

Delicate handling of tissue with laparoscopic instruments by the main surgeon and the assistants is essential to avoiding this complication. Atraumatic graspers should always be used when handling bowel. Likewise, it is important that all instruments be introduced under strict visual guidance into the peritoneal cavity. Instruments should never be left unattended and should be withdrawn from the abdominal cavity when not in use. Attentiveness, economy of motion, and deftness of touch are essential characteristics of the successful open and laparoscopic surgeon.

Vascular Injury.

Fortunately, direct major vascular injury during laparoscopic dissection is a rare event. The use of only blunt trocars, the small nature of the instrumentation, the limitations on surgical speed, and the magnification of the surgical field by the laparoscope minimize this potential problem.

During right renal dissection, in particular, the chance of a vena cava, renal vein, or gonadal vein injury is heightened. When this occurs, the surgeon can undertake several steps to resolve the bleeding. **First, the pneumoperitoneum pressure can be raised to 25 mm Hg, thereby slowing or stopping any venous bleeding.** With the use of the irrigator-aspirator, the blood can be cleared and the bleeding site identified. Next, through one of the 12-mm ports, a gauze sponge or pledget can be introduced into the abdomen and handled with a grasping forceps, thereby allowing the surgeon to identify and tamponade the area of bleeding. If the injury is small, then it may respond simply to direct pressure. Alternatively, surgical pharmaceuticals such as fibrin glue or gelatin matrix thrombin sealant (e.g., Floseal [Baxter, Deerfield, IL]) may be applied. If the injury is larger, then the surgeon must decide whether to convert to an open or hand-assist procedure or to attempt to secure and repair the injury laparoscopically. Depending on the severity of injury, a vascular surgery consultation may be appropriate. If a laparoscopic repair is attempted, intracorporeal suturing and possibly the use of a laparoscopic Satinsky clamp may be required. Throughout this period, it is essential for the anesthesiologist to administer sufficient fluids or blood replacement to preclude a hypovolemic state because the hypovolemic patient has a higher risk of possible air embolism at these higher intra-abdominal pressures (O'Sullivan et al., 1997).

If the surgeon is able to gain temporary control of the vessel with a grasper, then it is often helpful to place an extra 5-mm port that can be used by the assistant for suction and irrigation or to optimize the plan of approach to the injury, thereby facilitating laparoscopic suturing. Either way, the additional port allows the surgeon to repair the bleeding site using two hands and with excellent visualization of the surgical field.

Alternatively, the surgeon can convert from standard laparoscopy to a hand-assisted approach. The hand, in this case, is valuable because it can rapidly tamponade the bleeding site. In this regard it is recommended, if at all possible, to pinch the sidewalls of the vein (e.g., inferior vena cava) closed rather than just putting direct pressure on the top of the injury; the latter approach has a tendency to result in a gradual enlargement of the hole in the vein. Also, if the hole is pinched closed, a Satinsky clamp can be more easily passed beneath the surgeon's fingers to provide reliable control of the injury in preparation for a sutured repair.

Minor arterial injuries usually respond to tamponade. Larger aortic or renal artery injuries are much more difficult to resolve laparoscopically. Although the latter, if it occurs during a planned nephrectomy, can be handled by expeditiously taking the renal artery with a vascular stapler, the former may lead to immediate conversion and open repair. As mentioned earlier, addition of an additional 5-mm port can be very useful to help establish a clear field and allow the surgeon use of two hands to control the injury. If conversion to an open procedure is necessary, the area of injury should be tamponaded with laparoscopic forceps, and the surgeon can proceed to rapidly make a midline or subcostal incision by swinging one of the ports up to the underside of the abdominal wall and cutting down on the shaft of the port. The tamponading laparoscopic forceps are important to directing the surgeon immediately to the site of injury, which can then be properly repaired. Again, a vascular surgeon should be called into the room as necessary.

As mentioned previously in this chapter, because most bleeding episodes are unexpected, it is wise to have in the room a hemorrhage tray equipped

with all instruments necessary to control bleeding and for potential open conversion (see Box 14.3).

Nerve Injury.

Nerve injury is invariably a result of patient positioning in combination with the duration of the procedure. The exact incidence of this problem is not known. A survey of neuromuscular injuries associated with laparoscopic urologic surgery completed by 18 urologists from 15 institutions in the United States, published in 2000, found that in a total of 1651 procedures there were 46 neuromuscular injuries in 45 patients (2.8%) (Wolf et al., 2000).

If the patient is inadequately positioned and/or padded, nerve damage may result from abnormal nerve stretching or compression. Among position-related nerve injuries, the brachial plexus appears to be most at risk. Injury may be inflicted in several ways: (1) abduction of the arm beyond 90 degrees, (2) extreme outward rotation of the head of the humerus, and (3) compression damage when shoulder braces are used in the Trendelenburg position (Phong and Koh, 2007), which pushes the clavicle into the retroclavicular space. In particular, this has been reported as a problem with robotic radical prostatectomy when a steep Trendelenburg position is required and strapping the patient may be necessary to avoid slippage. Other nerves that can be affected by positioning include the femoral nerve, because of extreme lateral rotation and abduction of the hip joint, specifically in the lithotomy position, and the sciatic nerve, because of stretching along the superior leg when the patient is in the lateral decubitus position (Abdel-Meguid and Gomella, 1996; Hershlag et al., 1990; Liss et al., 2013). In addition, nerves may be injured during the surgery because of either direct mechanical injury or monopolar electrosurgical current.

Nerve palsy caused by positioning is recognized only postoperatively, often on the first postoperative day when the patient tries to ambulate. From a medical and a legal standpoint, a neurology consultation should be obtained as soon as the patient calls the surgeon's attention to a possible nerve injury. Neurologic examination with possible nerve conduction studies to document acute damage is important. Physical therapy may facilitate recovery. However, recovery in these cases, if it does not occur within the first few postoperative days, is often slow, requiring months.

Prevention is paramount. Table-mounted accessories for all major commercial operating room tables aid in safely and effectively positioning patients in the lateral decubitus position and in the prone position. If the arms are to be at the patient's sides, they should be pronated to protect the brachial plexus. If the patient is to be in a lateral decubitus position, all bony prominences should be padded with additional gel pads (i.e., hip, knee, and ankle on the downside leg), and a pillow is always placed between the legs. Padding should also be placed beneath Velcro straps and tape, which may be used on the upside hip and shoulder. If the patient is in the lithotomy position with steep Trendelenburg, as is often required during laparoscopic or robotic radical prostatectomy, shoulder braces should not be used because of the risk of brachial plexus injury. Instead, use of well-padded wide straps directly across the upper chest and use of the surgical beanbag (Carey and Leveillee, 2007) are excellent ways to secure the patient. Extreme abduction of the hip is also to be avoided; meticulous care to position the patient with attention to hip flexion should be taken when the patient is placed in lithotomy for a prolonged period. Padding must be checked each time the table position is changed, and the patient should be rechecked if he or she is suspected of sliding on the table.

Injury to the Urinary Tract, Spleen, or Pancreas.

Similar to open surgery, during laparoscopic or robotic surgical procedures the urinary tract, spleen, or pancreas may be injured.

Injury to the Urinary Tract

Bladder Injury.

Electrocautery and blunt, sharp, and laser dissection have been identified as intraoperative causes of bladder injury (Ostrzenski and Ostrzenska, 1998). Concomitant bladder or pelvic anomalies or pathologic conditions (prior pelvic or bladder surgery, endometriosis, malignant infiltration, bladder diverticula, amyloidosis, or previous radiation) are predisposing factors that increase the chances of this bladder injury (Ostrzenski and Ostrzenska, 1998).

When a bladder injury has occurred, the intraoperative signs may be subtle. One of the first signs is the presence of blood or gas in the Foley catheter bag. Also, the surgeon may notice clear fluid welling up in the pelvis, although this sign is often obscured if irrigation has been used during the procedure.

Postoperatively, if the bladder injury was missed, the patient may develop oliguria and urinary ascites; this may be accompanied by hyponatremia and, rarely, hyperkalemia with mild elevation of the serum creatinine concentration caused by the peritoneal absorption of urine. Patients who have been discharged from the hospital because of the minor nature of their laparoscopic procedure may contact their physician and complain of lower abdominal discomfort, abdominal swelling, fever, and, in the case of a gynecologic procedure, vaginal discharge.

An air-expanded urine collection bag initially may arouse intraoperative suspicion of a bladder injury; this presumptive diagnosis can be confirmed by the injection of saline mixed with indigo carmine through the Foley catheter. Postoperatively, the diagnosis can be made by conventional cystogram or CT cystogram.

The intraoperative diagnosis of a bladder injury can be followed by laparoscopic repair, either suturing with absorbable suture or, if the injury is small, using preformed suture loops to encircle and secure the cystotomy (Ostrzenski and Ostrzenska, 1998; Poffenberger, 1996). More extensive defects may require open repair.

When bladder injury is diagnosed postoperatively, the key factor is whether the drainage is extraperitoneal or intraperitoneal, which is largely dependent on the preceding laparoscopic access. Extraperitoneal extravasation without any complicating additional problems may be treated by simple placement of a transurethral indwelling Foley catheter. Intraperitoneal drainage is an indication for subsequent laparoscopic or open repair.

Prevention of bladder injury begins with preoperative placement of a Foley catheter. Avoidance of excessive coagulation near the bladder and dissection with exact knowledge of bladder anatomy (urachus, medial umbilical, and vesicocervical ligaments) are also key.

Ureteral Injury.

Ureteral injury is usually a result of thermal damage caused by dissection using monopolar electrocautery in the immediate vicinity of the ureter. Its incidence in laparoscopic hysterectomy is 1%; it may also occur during laparoscopic endometriosis ablation and tubal ligation and has been reported during pelvic lymphadenectomy and laparoscopic and robotic radical prostatectomy (Baumann et al., 1988; Grainger et al., 1990; Guillonneau et al., 2002; Jhaveri et al., 2014; Liu et al., 1997; Ostrzenski and Ostrzenska, 1998; Poffenberger, 1996; Yuh et al., 2014).

Typically, ureteral injuries remain unnoticed throughout the laparoscopic procedure. As opposed to a bladder injury, macroscopic hematuria or pneumaturia is distinctly unusual with this injury. The astute laparoscopist or robotic surgeon may make the diagnosis intraoperatively when urine is seen to be welling up in the wound. However, if irrigation has been used during the procedure, this sign is invariably obscured. Within 2 to 3 days after surgery, patients may have abdominal and/or flank pain, fever, signs of peritonitis, and leukocytosis (Grainger et al., 1990; Liu and McFadden, 2000).

The diagnosis of ureteral injury is most often made during the postoperative period when a contrast-enhanced abdominal or pelvic CT scan with delayed images is ordered because of the patient's complaint of flank pain, abdominal swelling, hematuria, urinary leakage from the wound, and/or the physical signs of urinary ascites. Depending on the function of the contralateral kidney and the amount of urine leakage, serum chemistries may reveal hyponatremia and, rarely, hyperkalemia with a mild elevation in the serum creatinine concentration.

If identified intraoperatively, the injury can be repaired laparoscopically or robotically, but conversion to an open procedure may be required. If the problem is detected in the postoperative period, the first step is to place an indwelling ureteral stent and a bladder catheter. If a stent cannot be placed, then a percutaneous nephrostomy should be placed and an antegrade attempt at stent placement can be made. Depending on the severity of injury, either early laparoscopic or open surgical intervention may be indicated rather than a conservative approach.

Prevention of this injury again highlights the importance of the surgeon's knowledge of anatomy and the course of the ureter with regard to its topographic relation to other anatomic structures (medial umbilical ligament, round ligament or vas deferens, and common iliac artery). During dissection, monopolar electrosurgical coagulation current should be used with great discretion around the ureter. Ideally, fine-tipped electrosurgical instruments should be used and the duration of discharge should be brief (i.e., multiple short bursts of current rather than a continuous multisecond discharge).

Pancreatic Injury.

Injury to the pancreas during left-sided laparoscopic adrenalectomy or radical nephrectomy is most commonly associated with mechanical retraction. The tail of the pancreas overlies the adrenal and may be injured during dissection of the medial aspect of the adrenal and division of the splenorenal ligament. The incidence of this complication is 2.1% for radical left nephrectomy and 8.6% for left adrenalectomy (Varkarakis et al., 2004). The diagnosis is rarely made intraoperatively, with 75% of pancreatic injuries diagnosed postoperatively.

The typical presentation is postoperatively with abdominal discomfort, elevated serum lipase and amylase levels, and leukocytosis. CT reveals a fluid collection that can often be drained percutaneously. A nasogastric tube is placed and oral intake is stopped. When drainage drops below 50 mL/24 h, the drain can be removed, followed by removal of the nasogastric tube and initiation of a low-fat diet.

Prevention of this complication requires the surgeon to widely dissect the line of Toldt and the splenophrenic attachments. The latter are freed to the level of the diaphragm. The colon is broadly reflected from the Gerota fascia, and the splenocolic and splenorenal ligaments are divided. With these maneuvers the spleen and colon rotate medially, carrying with them the tail of the pancreas, well away from the medial surface of the adrenal gland.

Splenic Injury.

The advent of laparoscopic surgery has been associated with a significant decrease in incidental splenectomy during left nephrectomy, with a fall from 4.3% to only 1.5% (Breda et al., 2009; Cooper et al., 1996). These injuries are invariably discovered intraoperatively and can effectively be treated with argon beam coagulation or with one of the newer hemostatic agents such as fibrin glue or thrombin-impregnated granules. **Avoidance of this complication is best achieved by wide mobilization of the spleen during left nephrectomy.** To this end the splenophrenic attachments, as well as the splenocolic and splenorenal ligaments, must be divided. Retraction in the area of the spleen should never be on the spleen but beneath the area of the splenocolic ligament so that the retractor is placed on these thicker tissues (Cooper et al., 1996; Simon et al., 2004).

Complications Related to Exiting the Abdomen

Bowel Entrapment.

During removal of laparoscopic ports and desufflation of the pneumoperitoneum, omentum or bowel may be entrapped at one of the port sites. If missed during the process of cannula removal, then in the early postoperative period, usually on the second or third postoperative day, the patient may develop an ileus and point tenderness at the port site incision.

The treatment is operative. The pneumoperitoneum is reestablished through one of the unaffected port sites, and three ports are replaced: one for the camera and two for grasping forceps. The entrapped bowel is visualized, and an atraumatic bowel clamp is placed on the bowel on either side of the area of herniation. Once this is done, the skin sutures of the affected port site are carefully cut and the wound is opened. The surgeon uses a fingertip to manually reduce the bowel into the abdominal cavity. The bowel can then be carefully inspected; if it appears viable, which is usually the case, it can be left in place and the port site closed. Rarely are formal bowel resection and reanastomosis required.

Bowel entrapment is the result of a technical error. Indeed, most laparoscopic ports have a hole drilled into the side of the port within a few millimeters of the end of the port's shaft. This hole equalizes the pressure in the port and the abdomen as the port is pulled out of the abdomen, thereby precluding any bowel being withdrawn with the port. Furthermore, if each port site is endoscopically inspected at the time of cannula removal, bowel or omentum that may have entered the port site can be readily identified and positioned back into the abdominal cavity. When the last endoscope-bearing port is removed, the assistant should pull up on the closure sutures or on a fascial clamp, and the surgeon should back the cannula out of the wound and up onto the shaft of the endoscope so that the endoscope is the last thing to leave the abdomen.

Bleeding at the Sheath Site.

Bleeding at the sheath site was previously discussed under Complications Related to Placement of Secondary Trocars. However, there are times when this problem does not become apparent until the end of the procedure as a result of tamponade from the trocar. Again, it is essential to inspect each trocar site at 5 mm Hg to rule out this problem.

Early Postoperative Complications

Pain.

Pain may be localized or diffuse. Early in the postoperative course, port site discomfort is to be expected. However, if postoperative pain is limited to a port site, it may also be secondary to herniation (immediate or late), bowel injury, or infection (late). Localized pain combined with a subcutaneous bulge may indicate a rectus sheath hematoma, bleeding and hematoma formation at a port site, or a port site hernia. Pain at a port site without swelling may be due to a particularly broad fascial suture or palpation of the knot of a port site fascial suture in a thin patient. Ultimately, if port site pain appears to be increasing on subsequent postoperative days, herniation should be suspected.

Immediate, severe, diffuse abdominal pain may be related to the release of noxious material during the procedure (e.g., cyst fluid in patients with autosomal-dominant polycystic kidney disease) or to a bowel injury. Immediate postoperative scapular discomfort may be a result of the CO_2 pneumoperitoneum causing some irritation of the diaphragm. Rarely, this discomfort may be sufficiently severe to mimic the symptoms of a pulmonary embolus. This pain is invariably along the area of the right posterior shoulder region. Delayed diffuse abdominal discomfort and development of peritoneal signs or simply ongoing abdominal discomfort accompanied by low-grade fever may be results of an unsuspected bowel injury.

Incisional Hernia.

In adults, the occurrence of an incisional hernia is usually confined to port sites larger than 10 mm. However, in the pediatric population, this complication can occur even with 5-mm ports. The patient usually reports localized discomfort accompanied by nausea and signs of ileus. Rarely, diffuse abdominal pain and/or signs of a complete bowel obstruction may be present. Examination reveals tenderness and, at times, swelling overlying the affected port site. A plain film of the abdomen may show an ileus pattern; however, the definitive study is abdominal CT, which can actually reveal the bowel protruding above the fascial level.

Laparoscopic repair with dissection of the hernia and subsequent intra-abdominal closure can be accomplished. The method for performing this procedure has already been described. In complicated cases in which a strangulated hernia is suspected or confirmed laparoscopically, general surgical consultation should be sought.

As discussed previously, **the risk of incisional hernia can be greatly reduced by using nonbladed as opposed to bladed trocars.** When bladed trocars are used, hernias can be avoided by performing a meticulous fascial suture closure of all trocar entry sites 10 mm or larger in all adults. In children, it is advisable to perform fascial closure of any “bladed” port site 5 mm or larger. The fascial layer is usually closed with an absorbable suture as previously described. **For patients in whom only nonbladed trocars have been used, fascial closure is indicated only of midline ports 10 mm or larger** (Kang et al., 2012) **or any port site that has been unduly stretched.** Indeed, some authors recommend no closure even of midline nonbladed trocar sites (Siqueira et al., 2004). Although there have been a few reports of a hernia developing after use of a nonbladed trocar (Kouba et al., 2007; Lowry et al., 2003; Zemet et al., 2012), this is distinctly rare. Indeed, the incidence of postoperative hernia formation fell from 1.8% with bladed trocars to only 0.19% for nonbladed trocars (Boike et al., 1995; Hashizume and Sugimachi, 1997; Thomas et al., 2003). With midline hand-assist approaches, a higher incidence of hernia formation has been identified than would otherwise be expected: 4.0% to 7.3% (Troxel and Das, 2005). Therefore some authors have recommended closure of this midline incision with interrupted nonabsorbable suture rather than a running closure (Troxel and Das, 2005).

In addition, transverse midline fascial incision has been shown to be superior to vertical midline fascial incision for reducing hernia risk (Brown and Goodfellow, 2005; Halm et al., 2009). Specifically, for robotic radical prostatectomy the change from vertical to horizontal incisions for the camera port and subsequent prostate removal port site has resulted in a reduction in incisional hernias of 5.4% to 0.4% (Liss et al., 2013).

Deep Venous Thrombosis and Pulmonary Embolism.

Although it seems reasonable to expect decreased venous return and therefore increased stasis with concomitant higher risk of deep venous thrombosis (DVT) and pulmonary embolism (PE) in patients undergoing laparoscopy, this is remarkably **not** the case. Indeed, there is no evidence that this complication occurs more often during laparoscopic or robotic procedures versus open surgery (Abdel-Meguid and Gomella, 1996; Secin et al., 2008).

Thus far there have been no randomized controlled trials addressing the issue of DVT prophylaxis in patients undergoing laparoscopic and robotic surgery. **The American Urological Association has released a Best Practice Policy Statement for the prevention of DVT in patients undergoing urologic surgery. Noting the lack of data available directly pertaining to laparoscopic and robotic surgery, the panel recommended the use of pneumatic compression stockings placed at the time of laparoscopic procedure for all patients. In addition, they acknowledged that certain high-risk groups may require the use of low-dose unfractionated heparin or low-molecular-weight heparin before, during, or after surgery.**

Pneumatic compression stockings should be placed preoperatively and continued for 48 to 72 hours postoperatively. In addition, in morbidly obese patients or in individuals at high risk for thrombosis (smoking, past history of DVT), the addition of unfractionated perioperative heparin (5000 units 2 hours preoperatively and then every 12 hours postoperatively) has also been recommended (Capan and Miller, 1999; Clagett et al., 1995; Secin et al., 2008). **With specific respect to upper retroperitoneal (renal, adrenal, ureter) laparoscopic procedures, at least one study** (Montgomery and Wolf, 2005) **indicated that sequential pneumatic compressive stockings provide equivalent DVT prophylaxis compared with subcutaneous fractionated heparin and that the use of subcutaneous heparin may increase the incidence of hemorrhagic complications.** However, it must be stressed that this was a nonrandomized study obtained from a prospective database augmented by retrospective chart review.

Wound Infections.

Overall, this is a rare complication with standard laparoscopy. However, with the hand-assist approach a higher incidence of wound infections has been noted. In one report the postoperative wound infection rate at the hand-assist site was 9% (Nelson and Wolf, 2002). Prevention of this complication is similar to open surgery and includes attention to antiseptic preparation and sterile draping of the abdominal wall, irrigation of each port site at the end of the procedure, and meticulous closure of the wound.

Rhabdomyolysis.

Rhabdomyolysis is a devastating complication after laparoscopic surgery. The exact incidence of this problem is not known, but one survey of neuromuscular injuries associated with laparoscopic urologic surgery found that of a total of 1651 procedures there were 6 cases (0.4%) of clinical rhabdomyolysis (Wolf et al., 2000). In another study, it was estimated that the occurrence of this problem among patients undergoing retroperitoneal laparoscopic procedures (e.g., renal, ureteral, adrenal) was higher, at 1% (Reisiger et al., 2005). Rhabdomyolysis is invariably associated with male patients undergoing longer laparoscopic renal procedures, especially if the kidney rest has been used for the entire case. Although extra padding applied to pressure areas can be useful in avoiding nerve compression and rhabdomyolysis, gel pads and foam egg crate padding have not been conclusively demonstrated to significantly reduce pressure on the patient's flank in the lateral position (Deane et al., 2008). As discussed previously, **male**

patients with a BMI of 25 or greater undergoing laparoscopic surgery in the lateral position with the kidney rest elevated and the table completely flexed are at highest risk of developing rhabdomyolysis as a result of flank pressure.

Rhabdomyolysis manifests immediately in the postanesthesia recovery room; the patient complains of severe pain in the downside hip area. Brown urine may also be noted. The serum creatine kinase value invariably exceeds 5000 units/dL.

Prevention of this problem is essential. This can, to some extent, be achieved by avoiding use of the kidney rest or using it for only the earliest part of the case (i.e., less than an hour) and avoiding prolonged periods of hypotension during the procedure (Cadeddu et al., 2001; Kuang et al., 2002; Parsons et al., 2004; Reisiger et al., 2005). Last, with increasing skill and experience, few procedures should proceed beyond 5 hours.

Late Postoperative Complications

Complications beyond the 3-week postoperative period are rare. These include primarily lymphatic complications and incisional hernia. The latter is addressed in the prior discussion because it can also appear as an early postoperative complication.

Lymphocele Formation.

Lymphocele formation is most commonly associated with pelvic procedures, such as pelvic lymph node dissection during radical prostatectomy (0.4% to 1.3% incidence) (Kavoussi et al., 1993; Liss et al., 2013) or with renal transplantation (0.6% to 18% incidence) (Bailey et al., 2003). The lymphocele may take weeks to develop and may occur despite a transperitoneal approach. Presentation may be by a mass effect, but the astute clinician should realize that it may also occur as a result of local compression causing lower extremity edema, and, in rare cases, venous thrombosis and PE. The lymphocele is diagnosed readily by CT. **Treatment is percutaneous drainage. Sclerosant therapy can be used to treat the lymphocele; however, if unsuccessful or if the lymphocele is not amenable to percutaneous drainage, then a transperitoneal laparoscopic marsupialization procedure is usually successful.** At the time of the procedure, a tag of omentum can be placed into the opening made in the lymphocele to try to prevent closure of the opening and recurrence.

Prevention of lymphocele formation requires meticulous attention to clipping suspected lymphatic structures. Monopolar electrocoagulation does not work well to seal lymphatics. Bipolar or harmonic devices have been shown to effectively seal lymphatic channels; however, the bipolar device created a seal that was 5- to 10-fold stronger than the harmonic device (Box et al., 2009).

Chylous Ascites.

After left-sided retroperitoneal surgery (i.e., left radical nephrectomy, donor nephrectomy), the patient may complain of a distended abdomen. Although this complaint is common in the initial few days after a laparoscopic procedure because of the pneumoperitoneum, irrigation fluid, and/or ileus, it is distinctly rare late in the patient's course. There is no associated fever, pain, or bowel dysfunction, and routine laboratory study findings are within normal limits. Usually the condition is self-limited and resolves without any intervention. If the presentation is not straightforward, then abdominal CT will reveal the underlying problem and allow diagnosis of the presence of ascites. If tapped, the fluid may reveal elevations in the level of lymphocytes, cholesterol, and triglycerides.

Treatment is usually dietary, with a low-fat, medium-chain triglyceride diet. One may also consider giving somatostatin or octreotide (Leibovitch et al., 2002; Negoro et al., 2006). In the rare situation in which the fluid does not resolve with these conservative measures or if the patient is symptomatic, the fluid can be tapped once or twice. If it continues to accumulate, then an open or laparoscopic exploration is undertaken. Once identified, the leaking lymphatic channel is dissected and secured with either suture or clips (Molina et al., 2003).

Prevention of this type of problem is extremely difficult because the lymphatics are not readily visible during the procedure. In particular with laparoscopic procedures, lymphatic leakage may be overlooked as result of tamponade by the pneumoperitoneum. To date, instances of postlaparoscopic chylous ascites have been cited only sparingly in the literature (He et al., 2011; Leibovitch et al., 2002; Molina et al., 2003; Negoro et al., 2006; Shafizadeh et al., 2002).

Training and Practicing Laparoscopic and Robotic Surgery

Surgeons learning how to perform laparoscopic procedures face several hurdles, including an altered 2D view of a 3D space, counterintuitive control of instruments, different ergonomic constraints, and an altered perspective of surgical anatomy (Piechaud and Pansadoro, 2006). Robotic surgical systems such as the da Vinci Robotic System overcome several of these issues by providing binocular, 3D vision, and intuitive instrument motion. However, the robotic system does have its own hurdles to overcome, such as complete lack of tactile feedback and a learning curve regarding the syncopation of the surgeon's console. In addition, much like life in general, the only thing constant about laparoscopic and robotic surgery is change. It is therefore necessary for minimally invasive surgeons, no matter how experienced, to master new skills and familiarize themselves with new technologies as they develop. With an ever-increasing emphasis on patient safety and operating room efficiency, new surgical skills and techniques should be developed and honed outside the operating room and then transferred into the operating room once proficiency has been developed. The tools and systems available for practicing and acquiring laparoscopic and robotic skills are detailed here.

Equipment for Practicing Laparoscopic and Robotic Surgery

A wide variety of practice models exist for laparoscopic and robotic surgery, ranging from inanimate laparoscopic training boxes to live animal and human cadaveric models. There has also been heightened interest in the development of computer-driven VR trainers that can be used to practice standard techniques and whole procedures. As a general premise, nonliving models should be used unless it is absolutely essential to have a live model.

Laparoscopic Training Boxes

The items necessary for a basic laparoscopic training box are a box with an opaque top that is suitable for placement of laparoscopic ports and a vision system consisting of a video monitor, a light source, and a camera or camera-lens combination (Fig. 14.31). Several commercially available training boxes are available, but the shortcomings are their high costs and limited access because they are often located in dedicated training facilities. However, with the widespread availability of mobile technology platforms and cost effectiveness of 3D printing, alternative options such as the iTrainer exist (Ruparel et al., 2014; Yoon et al., 2015). In general, the instruments and camera should be configured in a triangular fashion so that the camera lies between the right- and left-hand instruments. For optimal ergonomic positioning, the angle formed between the camera and the right- and left-hand instruments should be 25 to 45 degrees. In addition, the angle between the instruments and the horizontal plane should be less than 55 degrees (Frede et al., 1999). Some more formal training boxes have built-in camera holders so that one person can practice alone without the assistance of a "camera driver." When possible, however, a camera driver can adjust the lens and camera in, out, up, and down to match the motions of the surgeon. This is most helpful during more delicate maneuvers such as suturing in which panning the view from wide to close-up is essential. This gives the assistant the opportunity to practice "driving camera," which is also an essential skill for laparoscopy. Necessary instruments may include laparoscopic graspers, scissors, and dissectors or essentially any instrument necessary to meet the requirements of the training drill. Practice for basic suturing requires a pair of laparoscopic needle drivers and some suture. A 3-0 suture on an SH (small half) needle is best for general practice.

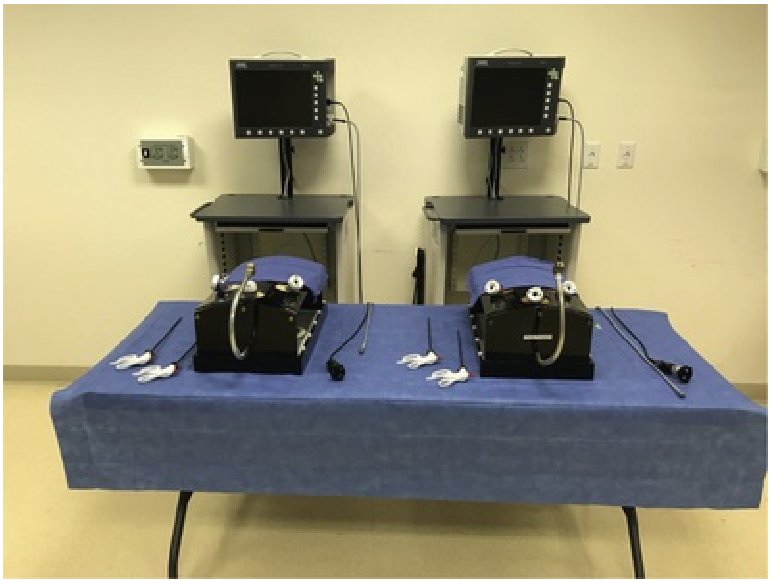

FIG. 14.31 Example of a standard laparoscopic training box with a monitor, camera-lens combination, and light source.

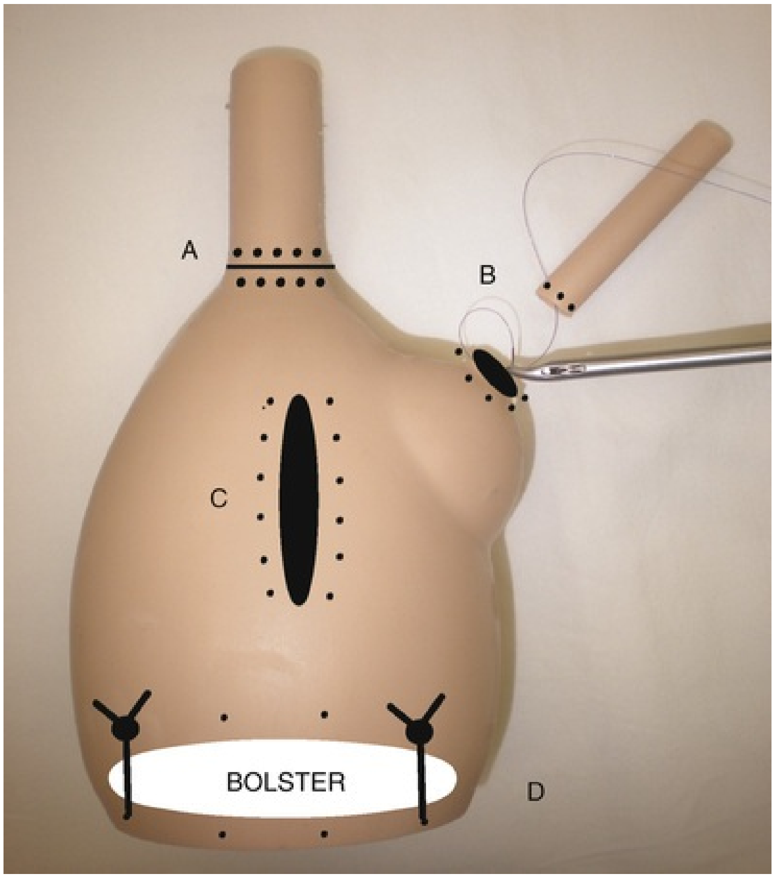
Whether simple or complex, inanimate training models can be placed within standard training boxes and act as the basis for general skill acquisition and progression. Training models for basic tasks such as touching areas of the box at different depths and heights within space, passing objects between instruments and through and around obstacles, and other helpful maneuvers such as cutting and tissue manipulation can be constructed from common materials such as paper, sponges, rubber gloves or tubing, and other commonly found materials. Alternatively, a variety of commercially available models are more realistic looking and may mimic actual operative scenarios more closely (eFig. 14.32).



EFIG. 14.32 Example of a task-specific training model LapED (4-in-1) model. This model can be used to practice four different urology-specific tasks: *A,* vesicourethral anastomosis; *B,* dismembered pyeloplasty anastomosis; *C,* closure of cystotomy; and *D,* renorrhaphy. (From Abraham JB, Abdelshehid CS, Lee HJ, et al.: LapED 4-in-1 silicone training aid for practicing laparoscopic skills and tasks: a preliminary evaluation. *J Endourol* 22:1351–1357, 2008.)

Alternatively, nonliving animal tissue can be placed within the box trainer for skill acquisition exercises. The advantage of using real, but nonliving, animal tissue to construct training models is that it creates a more realistic environment providing closer-to-life tissue handling. Generally the tissues used are inexpensive and can be purchased at a butcher shop or market. The disadvantage is that it requires more intense cleanup after practice. Generally the field inside the training box is set up to mimic a specific surgical scenario and develop specific skills. For instance, the stomach and esophagus of a chicken can be divided and then sewn back together laparoscopically to practice the fashioning of a vesicourethral anastomosis or pyeloplasty (Laguna et al., 2006; Ramachandran et al., 2008).

Live Animal Models.

The obvious advantage of use of live animal models is the opportunity to train under more realistic conditions, including more accurate anatomic relationships of tissue and the necessity for hemostasis that does not exist with inanimate models. The disadvantages of use of live animal models are that it requires extensive resources such as a veterinary facility, personnel to care for and provide anesthesia for the animals, and, eventually, euthanasia of the animals. Obviously this can be quite costly. For these reasons, practicing surgical skills on live animals is not appropriate for daily practice. Instead, these opportunities are usually reserved for formal training courses or when the need for a realistic environment warrants the necessary resources. In general, the species of animal used for practice must have a sufficient peritoneal compartment to provide an adequate working space. For fine procedures, animals as small as rabbits can be used. Swine are the most common animals used for laparoscopic and robotic training because they are readily available, they have the appropriate size peritoneal compartment, and their anatomy mimics relatively well that of humans. However, the amount of bleeding that comes from a pig kidney (e.g., in partial nephrectomy) is not realistic compared with that of a human. In addition, the porcine bladder is almost completely intraperitoneal.

Cadaveric Models.

One of the first experiences most medical students have in their training is anatomy, and this entails cadaveric dissection. The reason is simple. Short of operating on real patients, there is no better or more realistic way to learn human anatomy. This holds true for surgical practice as well: however, because of the major resources necessary to have an anatomic gift program and the significantly high cost for a cadaver compared with alternative models, it is often not practical to use cadavers. If, however, facilities and funding are available and there is a need for practicing a procedure in the most realistic environment, there is no substitute for cadaveric models.

Virtual Reality Trainers

VR trainers are computer-based simulators that offer the opportunity to practice laparoscopic and robotic skills through specific tasks, as well as whole procedures. Typically, trainees view the computer-generated operative field or training drill on a computer monitor and perform tasks using laparoscopic manipulators. The instruments are depicted on the viewer and correspond with the trainee's movements. A major advantage of VR trainers is that they can collect information regarding trainee performance and track progress over time in terms of precision, economy of motion, and other parameters of interest. Because the trainers are computer based, it is possible to develop training programs and curricula including didactics, videos, and live practice sessions. The trainee can progress through the curriculum based on performance. VR trainers have been shown to improve the skills of trainees, helping to prepare them for better performance during live surgery (Lucas et al., 2008; Seymour et al., 2002). In addition, a systematic review demonstrated that VR training appears to decrease the operating time and improve the operative performance of surgical trainees with limited laparoscopic experience when compared with no training or with box-trainer training (Nagendran et al., 2013). Several commercially produced VR trainers for robotics, laparoscopy, and even single port surgery are available (eFig. 14.33 shows an example) but are costly as a result of the advanced technology and software development necessary. The VR robotic trainers have been shown to have face, content, and construct validity (Abboudi et al., 2013). A recent observational study analyzing the European Urology hands-on-training courses in VR simulation found that benchmark scores derived from expert performances offer relevant and challenging scores for trainees to achieve during VR simulation and can be a useful educational tactic in residency training programs (Raison et al., 2017).

Formal Training Programs

Surgical competence is defined by technical and nontechnical skills (Hoznek et al., 2006). Traditionally these skills have been passed down from teacher to apprentice in the process of caring for and operating on real patients during residency training. The technical skills were taught during real operative procedures, and the nontechnical skills such as surgical judgment, problem anticipation and avoidance, and economy of motion, were gained by experience of the trainee with supervision from a more senior instructor. In this way, traditional residency programs have been more “learning” programs than “teaching” programs. With ever-increasing emphasis being placed on patient safety, operating room efficiency, and cost containment, there has been a great interest in evaluating the efficacy of formal training programs in laparoscopic and robotic surgery. Such programs offer the opportunity to receive formal instruction in a safe, stress-free environment with the intention of honing technical and nontechnical skills.

With this concept in mind, one method of concentrated instruction and skill acquisition is the “mini-residency” or “mini-fellowship.” In this training model, surgeons spend a period of several days (typically 5 days) receiving concentrated instruction on a given set of surgical skills or procedures, including didactic sessions, clinical case observation, and laboratory training using inanimate and animate models. Typically, the attendees also gain access to expert proctors during their initial learning curve for the new procedure. Mini-residency training has been shown to be effective in helping postgraduate urologists incorporate new laparoscopic and robotic procedures into their clinical practices. In one study of laparoscopic renal surgery mini-fellowship trainees at the University of California, Irvine, 73% of attendees were performing laparoscopic renal surgery 3 years later (Kolla et al., 2010). This was also found with robotic surgical training: of 47 urologists who took a 5-day training course for robotic radical prostatectomy, 90% were performing the procedure in their own practice at 3-year follow-up (Gamboa et al., 2009).

Key Points: Training and Practicing Laparoscopic and Robotic Surgery

- Laparoscopic VR trainers have been shown to improve the skills of trainees, helping to prepare them for better performance during live surgery.
- VR robotic trainers have been shown to have face, content, and construct

validity.

Conclusion

Laparoscopic procedures unthinkable in early 1990 are now performed routinely. Furthermore, the use of a robotic surgical platform to perform complex reconstructive procedures is improving the precision and often the outcomes of these operations and, more important, making it possible for a greater number of urologists to perform high-quality laparoscopic procedures. The widespread adoption of laparoscopy and robotic-assisted laparoscopy highlights the importance of having a detailed and robust understanding of the basics of minimally invasive surgery, including the physiologic effects of the pneumoperitoneum, obtaining access, and managing complications. The benefit will be more proficient laparoscopic and robotic surgeons who can handle any procedure and any complication without the massive incisions of years past and patients treated with a truly minimally invasive technique. Such should be the next step of our surgical path of discovery and evolution. At that point Osler's 20th century admonition, “Diseases that harm require treatments that harm less,” will be truly fulfilled. We are as yet still on the bridge to the future.

Acknowledgment

Special thanks to Dr. Michael Ordon for his previous contributions to this chapter.

Basic Energy Modalities in Urologic Surgery

Michael W. Sourial MD, FRCSC, Shubha K. De MD, FRCSC, Manoj Monga MD, FACS, Bodo Egon Knudsen MD, FRCSC

Tissue Dissection and Cauterization

Electrosurgery

Electrosurgery is the application of electrical current to tissue to achieve the effects of cutting, coagulation, desiccation, or fulguration. Monopolar and bipolar electrosurgery techniques are used in urology in numerous applications. An understanding of the basic scientific principles and tissue effects is necessary for the surgeon to use the technology in a safe and efficient manner. Although the technology can be of great assistance to the surgeon, improper settings or poor application can result in patient injury (Massarweh et al., 2006).

Electrosurgical technology was first developed in the late 1800s. The technology originated from spark gap transmitters that were used to generate radio waves at that time. The waveform produced was of a steady frequency but varied in amplitude. Using a combination of inductors and capacitors, the waveform could be smoothed out, although this resulted in some power loss. French scientists in the 1890s experimented with the technology and determined that the raw output from the spark gap transmitter could coagulate tissue, and the smoothed-out current could cut tissue. Around the turn of the 20th century, the technology began to be used in clinical surgical cases in Europe (Massarweh et al., 2006; Van Way, 2000).

In the 1920s Bovie, an electrical engineer at the Massachusetts Institute of Technology, studied the work of his predecessors and developed a cutting loop that delivered electrical energy that could be used for cutting, coagulation, and desiccation. On October 1, 1926, at the Peter Bent Brigham Hospital in Boston, Cushing used the device to remove a highly vascular myeloma from the head of a patient that previously had been deemed inoperable because of the vascularity of the mass (Massarweh et al., 2006; Van Way, 2000).

Monopolar Electrosurgery

Basic Physics.

Electrosurgery uses radiofrequency current in the range of 400,000 to 600,000 hertz (Hz) to pass through tissue and create the desired effects. The generators deliver more than 100 watts (W) of power to the tissue at voltages ranging from 100 to 5000 volts (V). As the current is delivered to the tissue, the tissue is heated, and the effect occurs. **In contrast, with electrocautery, the instrument is heated and then applied to the tissue. Ohm's law, current (I) = voltage (V)/resistance (R), applies and states that the current is determined by the applied voltage and the tissue's resistance.** The higher the resistance of the tissue, the greater the voltage needed to drive the current through the tissue. Current is calculated as the flow of electrons during a specific period of time. Voltage is used to drive the current through the resistance, which in surgery is the tissue. When alternating current is used, resistance is termed *impedance*. As the resistance increases, the amount of voltage to drive the same amount of current also increases. As tissues become cauterized, their impedance increases, and a higher voltage is needed for the current to penetrate the tissue beneath (Jones et al., 2006; Massarweh et al., 2006; Van Way, 2000; Van Way and Hinrichs, 2000).

Cutting and coagulation currents can be applied and use similar frequencies. **For coagulation to occur, the current is interrupted approximately 30,000 times per second. This interruption results in short bursts of radiofrequency energy. For cutting current, the radiofrequency current is delivered continuously** (Fig. 15.1). With continuous energy delivery, the cells heat up rapidly to the point of boiling and then rupture, which results in the cutting effect. With coagulation, because the energy is interrupted, the cells are allowed to cool as the energy is cycled off, and the cells dry out instead of rupturing (Jones et al., 2006; Massarweh et al., 2006; Van Way, 2000).

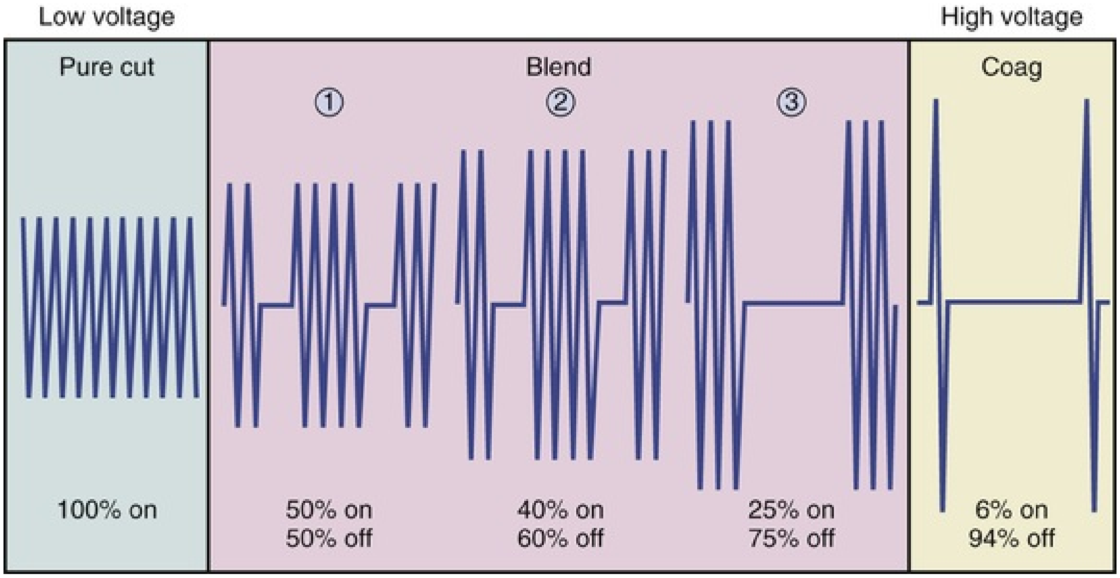

FIG. 15.1 Instrument settings relating voltage and current. Pure cut uses

continuous delivery, whereas coagulation uses interrupted delivery.
Blended modes modify the degree of interruption to desired effect.

Most generators also offer blended cutting, which adds some coagulation properties to the cutting current. This blended cutting is produced when the cutting current is interrupted similar to coagulation current. In contrast to coagulation current, where the generator output is concentrated into two or three cycles, blended cutting delivers more cycles to the tissue. The number of cycles delivered determines the degree of cutting versus coagulation. For example, a blend 1 setting may allow 50% of the current through, whereas a blend 3 setting may allow only 10% of the energy through, resulting in a greater coagulation effect (Jones et al., 2006; Massarweh et al., 2006; Van Way, 2000; Vilos and Rajakumar, 2013).

Modern electrosurgical generators are capable of high voltage and high wattage. This capability allows for either type of current to cut or coagulate. However, differences remain, and the coagulation current results in much more widespread tissue damage and charring but deeper hemostasis because of the higher voltages used compared with a lower voltage cutting current. **Cutting current employs voltages 10 to 20 times less than coagulation but is still greater than 100 V. Alternatively, coagulation current is delivered in short bursts at much higher voltage but with less current flow at the same amount of power.** The desiccation of the tissue results in increased impedance and lower current flow compared with cutting. Desiccation results in drying of the tissue and coagulation of blood vessels. The tissue is typically pale and dry with an eschar developing next to the electrode (Goddard et al., 1972; Jones et al., 2006; Massarweh et al., 2006; Van Way, 2000; Van Way and Hinrichs, 2000; Vilos and Rajakumar, 2013).

Fulguration results when the electrode is placed about 2 to 5 mm from the tissue. Electrical energy in the form of a spark arcs from the electrode to the tissue. A coagulation current setting on the generator usually is used, producing a darker char on the tissue with a superficial eschar. Fulguration can be effective at achieving hemostasis, but care must be taken to ensure the eschar is not too superficial, allowing for bleeding deeper in the tissue below the coagulum (Jones et al., 2006; Van Way, 2000).

Argon Beam Coagulator.

Traditional monopolar devices do not work well in a liquid environment, such as when there is significant blood in the targeted field. The fluid results in dispersion of the current, rendering it ineffective. To address this shortcoming, the argon beam coagulator was developed. **It works by adding a column of argon gas that passes over the electrode, and then electrosurgical energy ionizes the argon gas and helps to displace the blood in the surgical field. Because it is a noble gas, the current from the electrode is effectively transmitted to the underlying tissue.** The current follows the beam of gas and allows for diffuse superficial coagulation; this is ideal for obtaining hemostasis over a broad surface, such as during a partial nephrectomy. Typically, the argon beam coagulator is held slightly farther from the tissue at about 5 to 10 mm. It uses a standard generator and grounding pad but is operated at a higher power setting compared with traditional monopolar cautery in coagulation mode to desiccate the target tissues (Massarweh et al., 2006).

Generator Settings.

When adjusting the generator settings, it is important to set the generator at a high enough power setting to achieve effective cutting and coagulation. Setting the generator too low results in an inability of the electrode to cut the tissue and poor or limited effect of the coagulation. For coagulation to occur, approximately 30 to 50 W is needed. For cutting, setting the generator at 60 W is a reasonable starting point, subsequently adjusting the power as needed. Typically, fatty tissue is less conductive than muscle and may require higher settings of approximately 80 W. This information is intended as a rough guideline only; experience with individual generators varies (Massarweh et al., 2006; Van Way, 2000; Vilos and Rajakumar, 2013).

Although coagulation current may be used to “cut” tissue using lower power settings, it results in greater collateral damage compared with using a cutting setting. Although it may be reasonable to use coagulation when dividing muscle, it is better practice to use pure cut or cut on a blend setting to produce less charring and less ancillary tissue damage (Massarweh et al., 2006).

Safety

The incidence of electrosurgical injuries is estimated to be 2 to 5 per 1000 (Hulka et al., 1997; Loffer and Pent, 1975; Nduka et al., 1994). Understanding the principles of the electrosurgical devices and operating them within their safety parameters can help to decrease the risk of unintentional injuries.

During monopolar electrosurgery, the patient is part of a complete electrical circuit. Current is initially produced in the generator and is conducted over wires to the electrosurgical electrode. The electrode is used to deliver the current to the surgical site where it is focused. The current is distributed through the patient's body to the dispersive electrode (grounding pad), where it leaves the patient's body and travels over wires back to the generator to complete the circuit. **This system is designed to concentrate the energy at the tip of the electrode and then disperse it widely while traveling through the patient's body. If the current is allowed to concentrate in other locations, potential morbidity could ensue.**

Most electrosurgical injuries occur at the grounding pad site. Historically, the grounding pad was a metal plate that had contact gel applied to it before placing it in contact with the patient. Modern grounding pads are called dispersive electrodes and function in a similar but safer manner. The old-style metal grounding pads that were used with conductive gel could dry out during a case. Rather than have the current travel through a large contact patch, the dried-out pad could result in a very small contact patch that focused the current and resulted in electrical burns on the skin and underlying structures. Modern dispersive electrodes do not dry out and produce a safer, stable contact patch with the patient. Modern generators have a built-in self-test system that monitors the status of the dispersive electrode. If the generator becomes dislodged or loses contact in some way, the system shuts itself down and the ground fault warning is activated (Alkatout et al., 2012; Hutchisson et al., 1998; Nduka et al., 1994).

Injuries can ensue from inadvertent activation of the electrosurgical electrode. Injury can occur if a foot pedal is accidentally depressed and the electrode burns the drape or burns the patient at a site not intended. Handheld electrodes with a finger actuator are less likely to cause such an injury, although it is still possible. Other injuries can occur if electrosurgical energy is applied to unintended structures during surgery; this can occur when blood vessels and nerves are running close together. For example, the parasympathetic nerves that run near the prostate and are responsible for erections may be inadvertently injured when hemostasis is obtained with coagulation. During laparoscopic nephrectomy, the heel of a monopolar hook electrode may be inadvertently brought into contact with the bowel while activated, resulting in a bowel injury. Keeping the instruments in view, being aware of the surrounding structures, using low but effective power settings, and maintaining a general awareness of the instruments may help reduce such injuries.

The tissues of the body vary in their impedance (ability to conduct electrical energy). Structures such as blood vessels have lower impedance and preferentially conduct and concentrate current, whereas fat has high impedance. Tissue impedance is an important consideration when operating on structures such as the bowel, where current could get concentrated in the thin vascular pedicle that supports the structure. Current concentrated in the pedicle could damage the vascular supply to the tissue.

In patients with pacemakers or implantable cardioversion devices, the manufacturer should be consulted before surgery involving monopolar cautery to ensure that interference with the devices does not occur during surgery. The devices may have to be temporarily deactivated during the procedure (Madigan et al., 1999).

Prosthetic joints can also affect current conduction but are not an absolute contraindication to use of monopolar cautery. Ideally, the direct path of the electrical circuit should be directed away from the prosthetic joint. For example, if the patient has a right hip prosthesis, the dispersion electrode pad should be placed on the contralateral hip (Massarweh et al., 2006).

Insulation failures can occur if there is a breakdown in the insulating material that surrounds the electrosurgical electrode. Usually only the tip of the electrode is left without surrounding insulation, but if defects occur in other locations, the current may arc out in these spots leading to unintended injuries. Such an occurrence is more likely when higher-voltage coagulation modes are used. Reused instruments may be associated with such failures because the defects in the insulation may occur during the reprocessing, although disposable devices could also have defects (Massarweh et al., 2006). Several clinical reports of insulation failures during robotic-assisted laparoscopic surgery have been published (Cormier et al., 2012; Mues et al., 2011). A 33% failure rate of the first-generation robotic monopolar scissors tip cover accessory after one clinical use has been described (Engebretsen et al., 2013).

The surgeon is also at risk for electrosurgical burns. Surgical gloves do not provide much insulation from electrical current. Current can penetrate gloves when they become wet, through capacitance conducting, or when mechanical breakdown of the glove occurs (Tucker and Ferguson, 1991).

Capacitive Coupling.

Capacitive coupling is the transfer of energy within an electrical network by means of the capacitance between circuit nodes. Capacitive coupling occurs when two conductive elements are spaced apart by an insulator and energy is stored, creating an electrostatic field. When the net charge exceeds the

insulator's capacity, current is transmitted from the first conductor to the second. This occurrence is rare but can lead to complications during laparoscopic procedures using electrosurgery. When an active electrode that is surrounded by insulation is passed down a metal trocar, capacitive coupling can occur. However, it can also occur with plastic trocars. The injuries typically occur out of the surgeon's field of vision. An active electrode monitoring system and limiting the amount of time that high-voltage settings are used can decrease the risk of capacitive coupling (Jones et al., 2006; Tucker and Voyles, 1995; Vilos et al., 2001; Wang and Advincula, 2007).

General Safety Tips.

Using the lowest possible energy setting that achieves the desired surgical effect is the simplest of the basic principles for the safe use of electrosurgical instruments. Rather than starting at a high setting, the surgeon should slowly ramp up the energy setting until the desired effect is reached. With higher settings, the potential for arcing and capacitive coupling increases. The settings should not exceed settings recommended by the manufacturer.

During surgical use, the electrode tip can become coated with eschar, which causes an increase in impedance and can lead to arcing, spark generation, and ignition of the eschar. A scratch pad can be used to clean the eschar, but this can cause grooves to form on the electrode, which can promote further eschar buildup. Alternatively, a sponge can be used to clean the electrode tip. A sponge effectively clears the eschar and does not cause scratches to the electrode (Massarweh et al., 2006).

A common technique during open surgical procedures is for the surgeon to grasp a bleeding vessel with a forceps or hemostat and then have the assistant touch the instrument with the activated electrode of the Bovie; this delivers current through the instrument to the bleeding vessel. During these maneuvers, the surgeon must be careful not to touch the patient with his or her free hand. Doing so would create an alternative circuit that could allow the current to travel to a different part of the patient's body. Keeping a firm grasp on the forceps can also help to reduce the possibility of current traveling in an alternate path (Alkatout et al., 2012; Hutchisson et al., 1998; Jones et al., 2006).

Basic principles that should be observed include keeping the operating field neatly organized and not tangling cords when multiple corded instruments are used. Care should be taken not to wrap cords around metal instruments because insulation defects could lead to burns. The handheld electrodes should be secured in an insulated holster when not being used rather than resting them on the patient; this reduces the possibility of burns or injury through inadvertent activation (Massarweh et al., 2006).

Types of Electrosurgical Instruments

Monopolar Devices.

Electrosurgical instruments can be divided into two categories of delivery devices: monopolar and bipolar. For monopolar devices, the Bovie is the most widely used example and has broad applications in many surgical specialties, including urology. The size and shape of the electrode affect its interaction with the tissue. A smaller contact area results in higher current concentration, whereas a larger contact area results in the current being more dispersed. Greater power settings would be needed with the larger electrode to achieve a similar tissue effect. Many systems allow the surgeon to select the tip appropriate to the given procedure, and the tips can be changed if needed during the procedure to fit the application (Massarweh et al., 2006; Vilos and Rajakumar, 2013).

Bipolar Devices.

In contrast to monopolar systems in which a circuit is created by delivering the energy via an electrode and then removed from the patient using a dispersive electrode (grounding pad), **bipolar delivery does not require a dispersive electrode. Rather, the active and return electrodes are integrated in the delivery hand piece.** The tissue contained between the electrodes is the target tissue.

Bipolar “vessel sealing” devices have been developed that use computing technology built into the electrosurgical generators. These closed-looped feedback systems allow for vascular structures up to 7 mm in diameter to be fused and can help obviate the need for sutures, clips, or surgical staples. Several studies have confirmed the effectiveness of such devices demonstrating clinically equivalent burst pressures when compared with surgical staples, sutures, and titanium clips. Compared with the Harmonic scalpel, burst pressures were higher for vessels 4 to 7 mm in diameter (Harold et al., 2003; Kennedy et al., 1998; Landman et al., 2003; Takada et al., 2005). The LigaSure vessel sealing system (Covidien, Dublin, Ireland) has been used successfully for radical prostatectomy and cystectomy with a benefit in operating time and blood loss demonstrated compared with conventional vessel ligation. However, long-term damage to neurovascular structures was not addressed in these studies (Daskalopoulos et al., 2004; Sengupta and Webb, 2001).

Ultrasonic Instrumentation (High-Frequency Vibratory Device)

Ultrasonic devices offer an alternative to electrosurgical instruments. **These devices have elements that vibrate at ultrasonic frequencies of approximately 55,000 Hz. Mechanical energy and heat are generated, and these cause the denaturation of proteins and the formation of a coagulum that can seal small vessels. Depending on the instrument, vessels 2 to 3 mm in diameter can be sealed, and vessels up to 5 mm in diameter can be sealed with some newer instruments.** Newer instruments also produce less heat and charring to the surrounding tissue, limiting thermal injury. The heat generated is usually less than 80°C. The device is best applied to the tissue in a tension-free manner; this allows the instrument to divide the tissue effectively while coagulating at the same time, limiting blood loss. Aerosolized fatty droplets may develop as the tissue is divided, and this can negatively affect visualization through the laparoscope. Examples of such devices are the Ultra Shears (Covidien), Harmonic Scalpel (Ethicon Endo-Surgery, Johnson & Johnson, New Brunswick, NJ), and Thunderbeat (Olympus, Tokyo, Japan). Devices for open and laparoscopic surgery have been developed. The Harmonic scalpel has been shown to allow for effective tissue dissection and bleeding control during laparoscopic partial nephrectomy (Harris, 1978; Helal et al., 1997; Tremp et al., 2011).

Comparing Various Energy-Sealing Devices

There is a relative paucity of data comparing the safety and efficacy of the various energy-based sealing devices. Outcomes measured in studies include vessel sealing time, coagulation, transection of tissue, and ergonomics of the device. Potential disadvantages include collateral damage, variable burst pressures, the generation of potentially toxic vapors, and the high disposable costs.

In a study comparing the use of the LigaSure device with a Harmonic scalpel during laparoscopic radical prostatectomy, a benefit in functional outcomes including return to continence and erectile function was demonstrated in favor of the LigaSure device (Pastore et al., 2013). A study comparing the vessel sealing times and thermal spread of two bipolar vessel sealing systems (LigaSure and PK [Gyrus ACMI, Southborough, MA]) and an ultrasonic device (Harmonic scalpel) was performed. This study demonstrated that the two bipolar systems had faster vessel-sealing times with higher burst pressures compared with the ultrasonic device. However, the ultrasonic device had less thermal spread and smoke production (Lamberton et al., 2008). In a study comparing the histologic appearance of 40 renal tumor margins excised with cold scissors, LigaSure, and the Harmonic scalpel, despite some degree of cellular damage, the ability to determine whether cells at the margin were benign or malignant was not affected by using an energy-based bipolar or ultrasonic device (Phillips et al., 2008). The smoke plume produced by ultrasonic devices may also be less toxic compared with electrosurgically generated smoke (Fitzgerald et al., 2012).

Laser Instrumentation: Soft-Tissue Applications

A laser is a device that emits light through the process of optical amplification by the stimulated emission of electromagnetic radiation. The word *laser* is an acronym for "*l*ight *a*mplification by *s*timulated *e*mission of electromagnetic *r*adiation." In the 1980s lasers first became of interest to researchers and clinicians in urology, and at the present time a wide range of lasers are employed to treat various soft-tissue and stone conditions. Although the holmium:yttrium-aluminum-garnet (Ho:YAG) laser has become the accepted gold standard for the treatment of urinary calculi at this time, various wavelengths of lasers are employed to treat soft-tissue conditions such as stricture disease, benign prostatic hyperplasia (BPH), urothelial cell cancer, and genital skin lesions (Heinrich et al., 2010; Marks and Teichman, 2007; Zarrabi and Gross, 2011).

Lasers are a source of electromagnetic radiation that emit a beam of energy that may include nonoptical wavelengths and visible light. The properties of this light create the therapeutic effects used during surgical procedures. General components exist with all lasers, including an energy source, an active medium, and a resonant cavity. Light is generated with the active medium, which can be a solid, liquid, or gas. For the laser action to occur, most of the atoms or molecules within the active medium must be brought simultaneously to a higher energy state by an energy source; this is also referred to as pumping. The energy source energizes the atoms in the active medium and produces a population inversion, which is an excited state in which the atoms or molecules are primed for stimulated emission (Siegman, 1986; Troup, 1963).

Numerous types of energy sources drive lasers. Broadly, either electrical current or a different wavelength of light is used. The pump light can be generated by a flash lamp or a different wavelength laser. The specific energy source used depends on the type of laser; however, all are designed to produce laser light in a collimated beam (Siegman, 1986; Teichmann et al., 2007).

Light exists as electromagnetic waves representing spatial concentrations of energy. Each wave exists as a bundle of energy or as a particle called a *photon*. Photons are emitted and stimulate surrounding atoms and cause additional photons to be released. These have the same energy and travel in phase with the initial stimulating wave. The result is that the entire light is the same wavelength and travels in the same direction. The highly ordered, in-phase light arrangement is termed *coherence*. A long tube or cylinder is ideal for this process but not practical. A resonant cavity is created using mirrors to reflect light, allowing it to have many passes through the medium. A small portion of the amplified light escapes out of the resonant cavity and forms the beam of laser light (Stein, 1986; Stein and Kendall, 1984a; Welch et al., 1989).

Laser light has specific properties. It is monochromatic and of a single wavelength. The light is coherent with a uniform spatial relationship between all portions of the electromagnetic wave. It has directionality with minimal divergence, which allows it to maintain brightness over long distances. It is the high concentration of the bright laser light when focused on a small spot that gives it the properties to be a useful surgical tool but also a potential hazard (Stein and Kendall, 1984a; Welch et al., 1989).

The wavelength of laser light can vary and may be in the ultraviolet, the visible, or the infrared portions of the optical spectrum. Most lasers emit one or a couple of wavelengths; examples include the argon (488 nm—blue; 514 nm—green), the neodymium:YAG (Nd:YAG; 1064 nm and 1318 nm), and the Ho:YAG (2100 nm) lasers (Stein and Kendall, 1984a; Teichmann et al., 2007).

Pulsed and Continuous Wave Lasers

Depending on how the excitation energy is applied and how the laser cavity is configured, the output beam of laser light is either pulsed wave or continuous wave. The duration and energy of individual pulses can vary and depend on the type of laser. Pulses may be delivered individually, in groups, or continuously over a wide range of frequencies. A laser is considered continuous wave if the output emission is greater than 0.25 second. Clinically, a continuous wave laser delivers output that is continuous and of a constant amplitude; this allows for a stable, easy-to-control instrument. In contrast, a pulsed wave laser delivers bursts of energy, which works well for stone fragmentation but may be more difficult to control during soft-tissue interactions (Teichmann et al., 2007; Zarrabi and Gross, 2011).

The power of the laser is equal to the energy over time (P = energy/time or W = Joules per second [J/sec]), and a high degree of power can be reached with even a small amount of energy if very short pulses are used. Several techniques exist that can compress or shorten the pulse. Examples include Q-switching and mode locking. Q-switching involves interrupting the light beam in a controlled fashion so that the laser action is delayed until maximal population inversion has occurred in the active medium. It generates lower pulse repetition rates, higher pulse energy, and longer pulse duration compared with mode locking, another technique used to shorten the pulse. Mode locking, which can be combined with Q-switching, can create ultrashort pulses by fixing the way photons bounce back and forth in the resonant cavity. It can create very high power pulses because of their ultrashort duration (Stein and Kendall, 1984a; Teichmann et al., 2007; Zarrabi and Gross, 2011).

Delivery Systems

All medical lasers have a delivery system that allows for the laser energy to be directed to the intended target site. Delivery systems may be fixed rigid systems, such as articulating arms, or flexible systems, such as fiberoptic glass fibers. Fiberoptic systems are generally inexpensive and versatile; however, fiberoptic materials are unable to transmit all laser wavelengths. For example, the carbon dioxide (CO_2) laser, with a wavelength of 10.6 μm, does not pass through quartz or glass fiber optics, and instead a more rigid system composed of an articulating arm with a series of mirrors is employed. The final tissue interface usually contains a focusing device to optimize the laser energy delivery (Marks and Teichman, 2007; Stein and Kendall, 1984a, 1984b; Teichmann et al., 2007; Zarrabi and Gross, 2011).

Light-Tissue Interaction

Laser light is absorbed by tissue in a wavelength-dependent fashion. However, some of the light, independent of the wavelength, may be reflected by the boundary layer of the tissue. This light is lost for the surgical purpose and may cause heating and collateral damage in the surrounding tissue. The optical properties of the tissue and the surrounding irrigant can affect the degree of reflection. Because this process is not dependent on the wavelength, reflection is often not considered when selecting a wavelength for surgical lasers (Teichmann et al., 2007).

Some scattering of the laser energy may also occur. By scattering, some of the intended laser energy is taken out of the surgical field. The degree of scattering varies with the wavelength of the laser. Typically, lasers with shorter wavelengths have a much greater amount of scatter compared with lasers of longer wavelengths. This is an important consideration in selecting an appropriate laser for surgical applications (Teichmann et al., 2007).

The most important light-tissue interaction is absorption. When the laser beam enters into a medium in which it is absorbed, the intensity of the laser energy decreases in an exponential fashion that is consistent with Beer-Lambert law. This law states that a logarithmic dependence exists between the transmission of light through a substance, the product of the absorption coefficient of the substance, and the distance the light travels through the material. Absorbed laser energy is converted to heat and increases the temperature of the target tissue. If enough heat is generated, coagulation and subsequently vaporization can occur. A chromophore is required for absorption to occur. In the body, melanin, hemoglobin, and water are available chromophores; hemoglobin and water are most important for urologic applications (Teichmann et al., 2007; Zarrabi and Gross, 2011; Fig. 15.2).

Types of Lasers

Neodymium:Yttrium-Aluminum-Garnet.

The Nd:YAG laser has a wavelength of 1064 nm and has a tissue depth of penetration of about 1 cm. It has hemostatic and coagulative tissue properties. Historically it has been used in urology for the treatment of BPH with visual laser ablation of the prostate (VLAP) and interstitial laser coagulation of the prostate. During VLAP, a side-firing laser fiber is used to direct the laser beam at 60- to 90-degree angles. The fiber is held off the prostatic tissue, and an area of heat-induced coagulative necrosis is produced as the tissue is targeted. The coagulated tissue is not entirely cleared at the time of surgery, but rather a sloughing process occurs in the weeks after surgery with associated edema. Prolonged postoperative catheterization may be needed in 30% of individuals (Cowles et al., 1995; Muschter, 2003; Norris et al., 1993).

Interstitial laser coagulation of the prostate involves placing laser-diffusing fibers directly into the adenoma of the prostate and can be performed either transurethrally or via a perineal approach. Similar to VLAP, the tissue undergoes coagulative necrosis and subsequently atrophies. The procedure can be safely performed in anticoagulated patients, but significant postoperative tissue edema can occur. Prolonged periods of catheterization after surgery—often 7 to 21 days—are required because of the high risk of urinary retention. Published retreatment rates of up to 20% at 2 years and 50% at 54 months suggest poor long-term durability (Daehlin and Frugard, 2007; Perlmutter and Muschter, 1998). With the advent of newer laser technology and techniques, the use of the Nd:YAG laser for BPH has largely been abandoned.

Potassium Titanyl Phosphate.

The potassium titanyl phosphate (KTP) laser, commonly referred to as the "green light" laser, is a frequency-doubled Nd:YAG laser. The Nd:YAG laser beam is passed through a KTP crystal, which results in doubling of the frequency and halves the wavelength to 532 nm, resulting in a visibly green laser beam. This wavelength is strongly absorbed by hemoglobin and in well-vascularized tissue has only 1 to 2 mm of tissue penetration compared with 10 mm for the standard Nd:YAG laser. The KTP laser is widely used for photoselective vaporization of the prostate (PVP) in which the well-vascularized prostate tissue is treated in a noncontact fashion with a side-firing laser fiber. The targeted tissue quickly increases in temperature above the boiling point and is vaporized leaving behind a rim of coagulated tissue that provides a layer of hemostasis. In contrast to VLAP, the limited depth of tissue penetration results in less tissue edema, and prolonged catheterization is usually not required (Barber and Muir, 2004; McAllister and Gilling, 2004; Teichmann et al., 2007; Zarrabi and Gross, 2011).

The early KTP laser systems were low-powered 34-W systems and were used in conjunction with a standard Nd:YAG laser. A hybrid surgical technique evolved in which the surgeon first performed a VLAP with the Nd:YAG laser and then used the KTP laser to perform bladder neck incisions. The goal was to try to reduce the prolonged catheterization and bothersome postoperative lower urinary tract symptoms after standard VLAP (Barber and Muir, 2004). Subsequently, a higher-powered 60-W KTP laser was developed. This KTP laser was a pulsed wave system but allowed for rapid delivery of the pulses that simulated the effect of a continuous wave laser. This laser permitted the photoselective vaporization of the prostate procedure to be performed independently of the standard Nd:YAG laser. Further refinement resulted in the development of an 80-W and a 120-W KTP laser, which demonstrated favorable outcomes and complications comparable with traditional transurethral resection of the prostate (TURP) (Kuromatsu et al., 2006; Ruszat et al., 2008; Thangasamy et al., 2012; Zang et al., 2016). More recently, a 180-W GreenLight XPS laser has been shown to be more favorable compared with the 120-W laser with regard to reduced operative time, fiber use, and PSA-reduction, suggesting more cost-effective and efficient tissue removal (Ben-Zvi et al., 2013).

Lithium Triborate.

The 120-W lithium triborate (LBO) laser was developed to increase the efficiency of the tissue vaporization compared with the 80-W KTP laser, especially for men with large prostates in whom procedures remained time consuming (Wosnitzer and Rutman, 2009). The LBO remains a 532-nm wavelength laser. The higher power allows the distance between the fiber tip and the target prostate tissue to be increased to 3.0 mm versus 0.5 mm for the KTP laser. The greater distance may help preserve the laser fiber and make it technically easier to use. However, hemostasis with the higher-powered system appears to be less compared with the 80-W system (Heinrich et al., 2010). Most recently, a 180-W LBO laser that works in conjunction with a liquid-cooled fiber delivery system (GreenLight XPS, AMS, Minnetonka, MN) was developed to increase efficiency further. The European GOLIATH study confirmed efficacy similar to TURP, and a North American multicenter trial demonstrated shorter lasering and operating times for the 180-W system compared with 120-W systems (Bachmann et al., 2014; Hueber et al., 2013). However, a steeper learning curve has been reported with the 180-W systems, with up to 120 procedures needed to work through the process and handle the higher power of the system safely and effectively (Misrai et al., 2014). In one study, there was little change in clinical outcomes including total operating time, lasering time, energy utilization, and complications between the 180-W and the 120-W LBO laser in an experienced PVP surgeon (Campbell et al., 2013).

Diode.

Diode lasers with wavelengths of 808 to 980 nm are absorbed well in water and behave similarly to Nd:YAG lasers (Orihuela et al., 1996). However, the laser is much more efficient than the Nd:YAG and requires only a standard wall plug for operation; this allows for a smaller, more portable laser design with fewer cooling requirements. More recently, interest in the diode laser as a tool for the surgical management of BPH increased. The 980-nm diode laser was used when the higher-powered LBO lasers were found to be not as effective in terms of hemostasis compared with the older 80-W KTP lasers. The diode laser appears to provide better hemostasis compared with the LBO laser but has a higher complication rate; postoperative frequency and urgency and epididymitis have been associated with its use (Chiang et al., 2010). In a randomized controlled trial, PVP with a diode laser was considered as safe and effective as monopolar TURP at 3-month follow-up, with similar complication and functional results. PVP had the advantage of shorter hospitalization and catheter indwelling times and no need for discontinuation of anticoagulant therapy (Cetinkaya et al., 2015). Another study prospectively following 80 patients who underwent PVP with the diode laser demonstrated that improved symptom scores, maximum flow rate, and postvoid residual urine observed at 24 weeks remained virtually unchanged at 1 and 2 years (Miyazaki et al., 2017).

Holmium:YAG.

The Ho:YAG laser is a 2140-nm pulsed laser that is used for soft-tissue and lithotripsy applications in urology. **The 2140-nm wavelength is strongly absorbed in water, traveling only about 0.5 mm in the fluid medium, making it ideal for the urologic environment. In the prostate, the absorption depth is about 0.4 mm, resulting in a high-energy density that leads to the rapid vaporization of tissue.** Heat is also generated during this process and allows for coagulation of small blood vessels up to a depth of approximately 2 mm.

It is held that the onset of vaporization occurs in the irrigant that is adjacent to the tip of the laser fiber. With each pulse of the laser, a steam bubble of a few millimeters in diameter is created. The bubble is not visible because it is present for only about 500 µsec—about the same length of time as the laser pulse duration. During holmium laser enucleation of the prostate (HoLEP), the laser pulses create the steam bubbles, which lead to the separation of the prostatic adenoma from the capsule of the prostate. Tissue vaporization occurs and leads to the white fibrous appearance of the tissue. The heat generated during the process allows for hemostasis to occur in the adjacent tissue. For persistently bleeding vessels, the laser can be “defocused” by increasing the distance between the fiber tip and the target bleeding vessel; this results in only the coagulation effect occurring with limited or no vaporization.

Before the development of the HoLEP technique, the use of the Ho:YAG laser for the treatment of BPH went through a series of steps. Similar to the KTP laser, the Ho:YAG laser was initially combined with the Nd:YAG laser to perform hybrid techniques in which the Nd:YAG was used first to perform VLAP, and then the Ho:YAG was used to make bladder neck incisions that reduced the need for prolonged postoperative catheterization (Gilling and Fraundorfer, 1998). These hybrid techniques subsequently led to holmium laser ablation of the prostate in which the laser energy was used to vaporize the prostatic tissue. This was a relatively easy procedure to learn but did require a high-powered Ho:YAG laser (80 to 100 W) and a side-firing laser fiber. However, the rate of vaporization was slow, and long procedure times were needed to treat men with large prostates adequately. The side-firing fibers would also fail if held too closely to the tissue, likely because of thermal breakdown (Tan et al., 2003). The development of holmium laser resection of the prostate (HoLRP) followed. This technique involved cutting pieces of the prostate off as it was resected, similar to a TURP. The sizes of the pieces could be larger than typical TURP chips but had to be small enough to be able to irrigate them out of the bladder at the completion of the resection. This technique was more challenging than holmium laser ablation of the prostate and remained time-consuming in patients with large prostates (Cresswell et al., 1997).

The next development was HoLEP, in which the median and two lateral lobes are enucleated and pushed into the bladder in a manner mimicking an open prostatectomy. Before the introduction of an effective tissue morcellator, some surgeons employed a traditional transurethral resection loop to cut up the adenoma in the bladder after the enucleation was completed. However, the tissue morcellator streamlined this process, and although it still carries with it the risk of bladder injury, it would appear to be much safer and less cumbersome than using a transurethral resection loop. HoLEP is performed in an almost bloodless field as a result of the coagulation produced by the Ho:YAG wavelength but also as a result of the extensive blunt dissection from the tip of the endoscope, similar to the use of a surgeon's finger during an open retropubic prostatectomy (Elzayat and Elhilali, 2006). HoLEP has proven to be a highly effective procedure with durable long-term results in men undergoing surgical management of BPH. It is effective for a broad range of prostate sizes and can be performed in men on anticoagulation (Elzayat et al., 2005, 2006; Krambeck et al., 2010; Tyson and Lerner, 2009). However, adoption of HoLEP has been slowed by the steep learning curve and the availability of other techniques that are easier to learn (Bae et al., 2010).

More recently, higher-powered Ho:YAG lasers (100-W, 120-W) have also been used for stone lithotripsy. These can allow for higher-frequency settings at lower pulse energies. Newer lasers also allow for adjustments of pulse duration. In an in vitro dusting model, a longer laser pulse duration provided effective stone comminution with the advantage of reducing laser fiber tip degradation and stone retropulsion (Emiliani et al., 2017; Wollin et al., 2017). Lumenis (Yokneam, Israel) has developed a new technology for their Lumenis Pulse 120H laser dubbed the “Moses effect.” The laser pulse is modulated to first separate the water then deliver the remaining energy to the stone, thereby reducing energy loss and improving fragmentation while reducing stone retropulsion. The technology requires use of their special Moses laser fibers. In a preclinical study, the use of the Moses technology resulted in significantly reduced retropulsion (stone movement was reduced by 50 times) and more efficient laser lithotripsy. In vivo assessment also suggested less ureteral damage in a porcine model using the Moses mode compared with regular mode (Elhilali et al., 2017). Similar results were also demonstrated in a stone simulator model (Ibrahim et al., 2017).

Thulium:YAG.

The thulium:YAG (Thu:YAG) laser is a continuous wave laser operating at a wavelength of approximately 2000 nm. It differs from the Ho:YAG laser in that the thulium ions are excited by high-power laser diodes instead of flashlamp excitation as in the Ho:YAG. As a result, there is less heat generation and increased power efficiency by a factor of five with the Thu:YAG laser, and no special electrical installation is needed to operate the laser (Teichmann et al., 2007). The slightly shorter wavelength compared with the Ho:YAG laser results in slightly less depth of tissue penetration. The continuous wave output promotes more of a direct cutting action of the laser versus tissue tearing and splattering with the pulsed output of the Ho:YAG. As the tissue is cut with the Thu:YAG, a seam of coagulated tissue is created and produces hemostasis. The coagulated tissues retain some water for efficient absorption of the laser energy during subsequent tissue passes (Teichmann et al., 2007).

Similar to other lasers, the Thu:YAG has been used in a variety of ways to treat BPH. Early reports described a tangerine technique in which the prostate was cut into slices with the laser (Xia et al., 2005). Hybrid techniques involving vaporization and resection (vaporesection) were developed and shown to be effective (Bach et al., 2010). Thulium laser enucleation of the prostate followed and was demonstrated to have results similar to HoLEP (Lancono et al., 2012; Netsch et al., 2017; Zang et al., 2012).

In stone lithotripsy, there appears to be very little stone retropulsion with the Thu:YAG laser, even at higher energy settings (8 J) (Kamal et al., 2016).

Carbon Dioxide.

The CO_2 laser produces a beam of infrared light with a wavelength of 9.4 to 10.6 µm. It is strongly absorbed by water and used for numerous medical purposes including dermatologic applications. It is a continuous wave laser and highly efficient with a ratio of output power to pump power of 20%. The infrared beam is delivered with a rigid arm containing a series of mirrors (Malek, 1992; Stein and Kendall, 1984b). In urology, it is primarily used to treat skin lesions such as condyloma, but it is also used to treat penile carcinoma when an organ-preserving strategy is employed (Bandieramonte et al., 2008; Colecchia et al., 2009; Finkelstein, 1984).

Intracorporeal Lithotripters

Table 15.1 summarizes characteristics of commonly used intracorporeal lithotripters.

TABLE 15.1

EHL, Electrohydraulic lithotripsy; *Fr,* French; *Ho:YAG,* holmium:YAG.

Electrohydraulic Lithotripsy

Electrohydraulic lithotripsy (EHL) has been implemented in biliary, pancreatic, and renal calculi. Initially employed in 1950 for bladder stones using 9-Fr probes, renal applications through flexible ureteroscopy became possible with technologic advances. First described in 1988, at a time when laser fiber technology was unable to flex in the same way, EHL became an innovative strategy to treat lower pole kidney stones endoscopically. Since then, more contemporary modalities have improved efficiency while minimizing complication risks.

Physics and Mechanism of Action

Two electrodes are positioned at the tip of the probe, creating a spark when triggered. **Immersed in a liquid, the electrical spark creates an immediate transition from fluid to gas, creating a rapidly expanding plasma shockwave radiating from the spark outward 360 degrees. The collapse of this shockwave creates a cavitation bubble, which creates a secondary shockwave and high-pressure microjets** (Vorreuther et al., 1995).

By adjusting spark discharge, the electrical and subsequent acoustic fragmentation potential can be optimized. Vorreuther and Engelking (1992b) identified that higher-voltage shocks produce linearly increasing peak pressures and steeper shockwave fronts. Lower-capacity probes produced shorter currents and shorter sparks with more narrow pulse widths. Because fluid vaporization provides the force required for fragmentation, a small space between the probe and stone is recommended during fragmentation. Typically, 1 mm is required because increasing the probe-to-stone distance leads to exponential decreases in shockwave power.

Probes between 1.9 and 3.3 Fr are available. Thinner probes are considered more versatile because of their application in flexible and semirigid ureteroscopy. Reducing probe diameter does not clearly lessen fragmentation potential; however, durability is decreased (Elashry et al., 1996). Pressure generated by EHL probes is estimated using the following formula:

$$\begin{aligned}&\text{Maximum pressure}\\&\quad = \text{Energy}/(\text{Pulse duration} \times \text{Fiber cross-sectional diameter})\end{aligned}$$

Tissue Effect

Vorreuther et al. (1995) attempted to quantify tissue damage resulting from the use of a 3.3-Fr Wolf EHL probe. With use of freshly harvested human ureters, researchers measured histologic changes after direct contact with the EHL probe. At 100 mJ, only punctate mucosal injuries were noted, whereas increasing to 400 to 600 mJ caused superficial mechanical defects in the muscularis. Increasing the energy to 1000 mJ caused transmural perforations. Microscopically, no thermal injuries were noted, and defects appeared to be due to mechanical disruptions, although limited to the cross-sectional diameter of the probe. When constant energy levels were maintained, altering voltage and/or capacity did not affect the resulting histologic findings. No damage was encountered at a distance of 1 mm between the probe tip and mucosa, even at maximal energy and pulse rates (Vorreuther et al., 1995). In a porcine model, bladder exposure to varying energy and total pulse numbers was performed using a 3-Fr probe. Scanning electron microscopy identified that the depth of mechanical mucosal denudation correlated independently with the energy setting and number of delivered pulses (Wu et al., 1994).

When tested in an intact ureter, the probe tip was centered in the lumen, and no histologic damage was encountered at energy settings less than 500 mJ/pulse. When energy levels reached 1000 mJ, a single pulse could produce a 1-cm longitudinal ureteric perforation. Thought to be secondary to cavitation bubbles, which can reach 1.5 cm in diameter at greater than 1300 mJ, the rapid expansion effectively burst the ureter (Vorreuther et al., 1995). The safe use of this (and any other) lithotripter requires a working knowledge of the physics behind stone fragmentation and the collateral effects on surrounding fluid and tissues (Fig. 15.3).

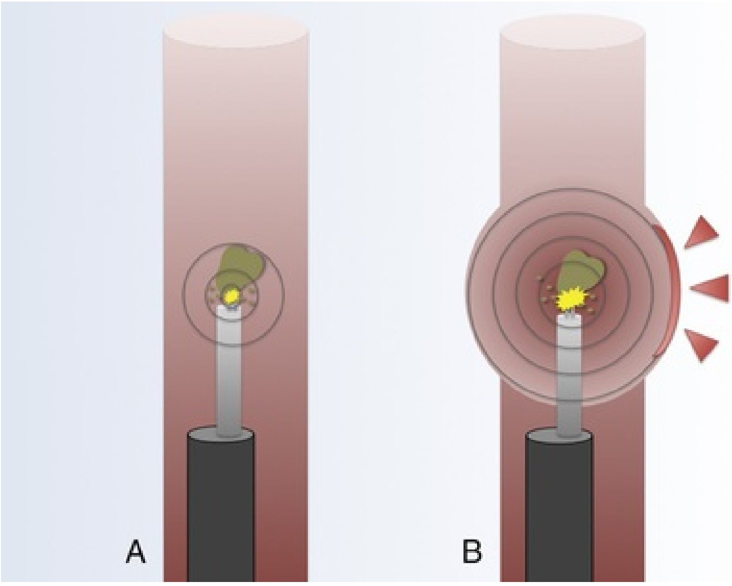

FIG. 15.3 (A) Electrohydraulic lithotripter probe spark producing a concentric shockwave within the ureter. (B) Higher energy settings create cavitation bubbles up to 1.5 cm, increasing the risk of ureteric injury and/or perforation.

Ureteroscopy

Initially, ureteral stone fragmentation with EHL was performed before the ability to visualize the upper urinary tract directly was available. When scope technology allowed adequate visualization with a sufficient working channel, EHL became a viable option for stone treatment (Goodfriend, 1984).

The collateral damage of EHL causing ureteral perforations during lithotripsy was reported in early studies using blind, fluoroscopically guided probe positioning and unreported energy settings (Goodfriend, 1984; Watson et al., 1987). In contrast, a series of 82 ureteroscopic cases using 2.4-Fr and 3.3-Fr probes through a 6.5-Fr semirigid ureteroscope reported no complications or perforations during lithotripter use and no strictures at 6 months (Vorreuther and Engelking, 1992a). **In 99% of cases, probe-to-stone contact was made, and using adjustable energy settings (265 to 1382 mJ/pulse), the average pulse energy was 450 mJ, resulting in 90% success rates.**

Elashry et al. (1996) performed a retrospective review of 45 patients failing extracorporeal shockwave lithotripsy (ESWL) who underwent EHL fragmentation. Performing 36 cases using flexible ureteroscopes (and a 1.9-Fr probe), 64% were interpolar and 17% were lower pole stones. Of the cases, 98% were considered successful (fragments <2 mm on direct visualization). Lower pole stones were effectively treated in 94% of patients, and at the time, laser fibers were not flexible enough to achieve active deflection into the lower pole. Another study of 114 patients undergoing flexible ureteroscopy confirmed the effective lower pole fragmentation by EHL; no statistical difference was noted between intrarenal stones based on location, and overall stone clearance rate was 80% (which decreased to 50% for stones >2 cm) (Dasgupta et al., 2004).

Larger stones have been successfully treated with flexible ureteroscopy and EHL when combined with Ho:YAG laser. Mariani (2007) reported on 15 patients with stones 2 to 4 cm (Kressel et al., 1992) and 17 patients with stones greater than 4 cm. With up to four outpatient treatment sessions, endoscopic management included laser lithotripsy to weaken large stones and EHL to debulk the fragments. The stone-free (fragments <4 mm) rate was 90%, and no reports of perforations or follow-up strictures were noted. Although not the current standard of care for stones of this size, with improvements in flexible scope and probe technology, larger stone burdens are commonly being attempted ureteroscopically.

Chemical stone composition has been shown to affect fragmentation efficiency during EHL ureteroscopy. A review of operating room times for 193 patients was compared with the chemical composition of ureteric stones. Uric acid stones required the most time, followed by calcium oxalate monohydrate, and in multivariate analysis, stone size was negatively associated with successful fragmentation (Song et al., 2012). This association may be due to the smooth outer surface and lamination of uric acid stones being more difficult for shockwave-generated fragmentation.

Bladder Stones

Cystolithotripsy was the initial application for EHL, and the reduced morbidity experienced with intracorporeal lithotripsy under direct vision was a major stepping-stone for endoscopy in urology. Although initial reports showed poor recurrence rates of bladder stones with EHL (50%) compared with vesicolithotomy (7.4%) (Short et al., 1984), very few complications were encountered. Since 1981, older patients were being treated, and cystolithotripsy was being combined with concurrent TURP (Bülow and Frohmüller, 1981). Because tip breakage and bladder perforations can still occur, it still must be used with caution (Bülow and Frohmüller, 1981; Pelander and Kaufman, 1980).

Key Points: Electrohydraulic Lithotripsy

- EHL probes create a spark, which produces a rapidly expanding plasma shockwave and cavitation bubble with high-pressure microjets.
- Increasing the distance from the target reduces its peak pressure exponentially.
- At less than 500 mJ, mucosal injuries are rare; at greater than 1000 mJ, the risk of tissue damage is increased.
- A 1.9-Fr probe can be used with flexible ureteroscopy and allows active deflection for acceptable rates of stone fragmentation in all calyces.
- Chemical stone composition and surface characteristics affect the efficiency of EHL fragmentation.

Pneumatic Lithotripsy

Pneumatic lithotripsy provides a versatile and dependable approach to urolithiasis throughout the genitourinary tract. Early clinical reports confirmed the efficacy of pneumatic lithotripsy, and success rates of 95% (Teh et al., 1998) have been reported. **With good fragmentation effect in hard stone compositions and attractive safety ratings, it continues to be popular globally in upper and lower tract stone disease.**

Basic Physics

Pneumatic lithotripsy uses ballistic forces to transfer kinetic energy from a handheld probe to the stone surface (Michel et al., 2008). Either compressed gas (medical air or CO_2 cartridges) or electromagnetic oscillations are used to drive a projectile forcefully against the probe tip, thrusting it forward like a piston. **Repetitive strikes (LithoClast [Boston Scientific, Marlborough, MA/Electro Medical Systems, Dallas, TX]), 12 Hz; electrokinetic lithotripter, 15 to 30 Hz) from the probe tip act as a jackhammer, fragmenting stones at the point of contact. When applied to compliant surfaces such as soft tissue, the impact energy is absorbed and dispersed, whereas rigid objects are not compliant, resulting in fracture.** Pneumatic lithotripters are safe for use in close proximity to the mucosa because soft-tissue injuries from probe contact are relatively mild (see following). Other advantages of pneumatic lithotripters are their durability, simplicity of use, and completely reusable components (Hofbauer et al., 1995). Adding to dependability are the successful fragmentation of all chemical stone composition (Teh et al., 1998) and the ability to use interchangeable probes to facilitate stone breakage anywhere in the genitourinary tract.

Probes are available in diameters of 0.8 mm (2.4 Fr), 1 mm (3 Fr), 1.6 mm (4.8 Fr), 2 mm (6 Fr), and 3.5 mm (10.5 Fr). In a head-to-head bench comparison of pneumatic (4.8-Fr probe, 2.5 bar), EHL (3-Fr probe, 80% power), laser (0.32-mm fiber, 100 mJ), and ultrasonic (4.5-Fr probe, power setting 3) lithotripters by Teh et al. (1998), fragmentation efficacy index (minutes per gram of fragmented stone) was compared. Pneumatic lithotripsy (5.00 ± 0.94 min/g) was the least efficient, whereas ultrasonic was the most efficient (8.49 ± 1.15 min/g), followed by laser (7.62 ± 0.78 min/g) and EHL lithotripters (6.60 ± 1.58

min/g). When probe sizes were increased at constant pressures (2 bar), incremental improvements in fragmentation were noted (3 Fr = 14 min/g, 6 Fr = 6 min/g). Pneumatic lithotripsy is effective in fragmenting harder stones and is less efficient in very soft stones; this is likely because the jackhammer effect produces numerous tiny fragments or because, in the case of extremely soft stones (i.e., matrix stones), the probe punches holes into stones without fragmentation.

Tissue Effects

A survival porcine model was used to test the short-term and long-term effects of 5- to 7-second bursts of LithoClast mucosal exposure to bladder and ureteric urothelium. A short duration was selected to simulate inadvertent contact experienced during stone fragmentation. Histologic changes in immediately sacrificed animals included focal areas of hemorrhage with mucosal erosions and transmural edema. At 3 and 6 weeks, the treated areas were unidentifiable, and histology failed to identify any significant changes. All animals experienced 24 to 48 hours of hematuria but failed to show any other systemic or diagnostic differences (Denstedt et al., 1995).

In a four-way comparison of intracorporeal lithotripters on iatrogenic urothelial trauma, Piergiovanni et al. (1994) **found perpendicular exposure to pneumatic probes to be the least traumatic (compared with laser, ultrasonic lithotripsy, and EHL).** Assessing perforation thresholds for each modality at 250 pulses, the 0.8-mm probe perforated ureteric walls, whereas larger probes (1- and 2-mm probes) were unable to perforate the ureter or bladder, regardless of total number of pulses.

Ureteroscopy

Thin pneumatic probes ranging from 0.8 to 1 mm are easily accommodated by ureteroscopes and are commonly used for semirigid ureteroscopy. Because of the high safety threshold, fragmentation efficacy, and cost effectiveness, it continues to be a popular modality. Comparing the shearing potential of four intracorporeal lithotripters on endoscopic baskets, **pneumatic devices are the only modality not to cut through wire** (Cordes et al., 2011). In ureteroscopy, where safety guidewires, trapped or hung baskets, and antiretropulsion devices may lie in close proximity to targeted stones, pneumatic lithotripters can provide an additional level of safety. Knowing that mucosal injury and wire damage are minimized with this technology may help provide confidence when aggressively treating difficult ureteric stones.

Probe size and pulse frequency settings can alter fracture efficiency. Even with the smallest diameter probes, hard stones can be fragmented through anterograde or retrograde ureteroscopy. An in vitro study using avian gut as a ureteric model examined the differing fragmentation rates of 5-mm phantom stones using different probes and settings. **Increasing probe diameter (0.8 to 1.6 mm) and pulse frequency (6 to 12 Hz) independently decreased the total number of required pulses to treat the stones completely** (Shadpour et al., 2009).

Stone migration is a significant disadvantage when treating ureteric stones because the ballistic effect of the probe can propel stones in capacious ureters into the kidney. Retropulsion has been reported in 10% of distal and 40% of proximal stones treated with pneumatic lithotripsy (Knispel et al., 1998). If flexible instruments are not readily available, stones washed into the kidney may require secondary procedures (i.e., ESWL). The risk of fragment migration is related to site, degree of impaction, size, lithotripsy modality, irrigation system, and degree of proximal ureteric dilation (Delvecchio et al., 2000; Hendlin et al., 2008; Lee et al., 2003). Antiretropulsion strategies such as stone pinning (between probe and urothelium), reverse Trendelenburg positioning, basket stabilization, and proximal placement of lidocaine gel may be used. Specific antiretropulsion products include the Stone Cone (Boston Scientific, Marlborough, MA), N Trap (Cook Urological, Spencer, IN), Passport Balloon (Boston Scientific), Parachute (Boston Scientific), Accordion (PercSys, Palo Alto, CA), and BackStop (Boston Scientific). Developed for markets where flexible instrumentation is not feasible, these products may help reduce the risk of stone migration (Bastawisy et al., 2011).

A randomized controlled trial of Ho:YAG laser (365 µm) and pneumatic lithotripsy (2.4-Fr probe) was performed in 79 patients undergoing semirigid ureteroscopy. Mean stone size was 12 mm, and most stones were located distally. Laser lithotripsy resulted in a superior stone-free rate at 1 month on radiographic and ultrasound follow-up (95% vs. 80.5%). Stone retropulsion was more common with pneumatic lithotripsy, and no significant complications were reported in either arm (Maghsoudi et al., 2008). A retrospective review of 500 patients treated from 1995 to 2002 showed that **stone-free rates are dramatically affected by stone position and size.** Stone-free rates for stones 10 mm or less were 97.1% for distal ureteric stones and 91% for proximal stones. For stones greater than 10 mm, distal stone-free rates were 89% for distal stones and 71.4% for proximal stones (Sözen et al., 2003). With a 6.4% overall complication rate, only 1.4% of patients developed mucosal injuries or perforations as a result of probe use.

Two series highlighted the safety of pneumatic lithotripsy in pregnant women with symptomatic ureteral stones (Abdel-Kader et al., 2013; Hoşcan et al., 2012). In both reports, the mean gestational age at presentation was 25 to 26 weeks, and most stones were located in the distal ureter. Using semirigid ureteroscopy, a stone-free rate of 85.3% to 100% was reported with no major anesthetic, surgical, or obstetric complications (Abdel-Kader et al., 2013). One patient developed premature contractions, which did not progress to early labor.

Ideally, a semirigid ureteroscope with a straight end on working channel should be used for pneumatic stone treatment because bending pneumatic probes reduce the transmitted energy from the generator to the stone (Grocela and Dretler, 1997). Although 2.4-Fr probes are flexible and can be accommodated by flexible ureteroscopes, an analysis by Zhu et al. (2000) quantified the energy loss secondary to probe bending. By measuring tip mechanics, impact momentum decreased 50% and energy by 76% when probe tips were deflected 33 degrees. With 48 degrees of deflection, only 30% of full fragmentation efficiency could be achieved.

Bladder Stones

Transurethral (Khosa et al., 2012; Rabani, 2012; Teh et al., 1998) **and percutaneous** (Agrawal et al., 1999; Wollin et al., 1999) **pneumatic lithotripsy have been found to be useful in large hard stones such as calcium oxalate monohydrate and cystine stones** (Denstedt et al., 1992). A retrospective series comparing ultrasonic, pneumatic, and mechanical lithotripsy for bladder stones showed equal efficacies for stones less than 3 cm (Razvi et al., 1996).

Khosa et al. (2012) reported a series of 100 children younger than 15 years old from Pakistan who underwent pneumatic cystolithotripsy using a 4-Fr “mini-scope” or a 7/8.5-Fr ureteroscope for bladder stones less than 3 cm. The average patient was 5 years old, and all surgeries were performed as outpatient procedures. Only 5% of patients developed hematuria, and one experienced postoperative urinary retention.

Cases of calcified foreign bodies such as encrusted ureteric stents (Grocela and Dretler, 1997) and eroded transobturator tapes (Osório et al., 2011) have been treated with pneumatic lithotripsy. An advantage of this modality with retained stents is that pneumatic lithotripters can be applied safely in transurethral or percutaneous cystolithotripsy, ureteroscopy, and percutaneous nephrolithotomy. Also, when stones abutted against the urothelium must be fragmented, pneumatic lithotripsy is safe to make contact with the urothelium for short periods.

Single setting TURP and percutaneous or transurethral pneumatic lithotripsy have been reported as treatments in patients in whom outlet obstruction is the precipitating cause of bladder stones (Aron et al., 2007; Sinik et al., 1998). Stone removal is performed initially, and if a percutaneous approach is used, the working sheath is maintained until after TURP to reduce the risk of extravasation. In a comparative analysis of patients undergoing either percutaneous or transurethral lithotripsy with simultaneous TURP, the percutaneous approach (using a 30-Fr sheath) decreased stone removal time by 45% and the need for secondary procedures (Tugcu et al., 2009). Patients who underwent purely transurethral procedures had their catheters removed earlier (2.2 days vs. 3.2 days) and had shorter admissions (1.2 days vs. 2.3 days); however, three patients (7.9%) developed subsequent urethral strictures.

Percutaneous Nephrolithotomy

Similar to treatment of bladder stones, percutaneous nephrolithotomy allows the use of larger scopes and larger probes. A Canadian trial comparing the StoneBreaker (Cook Urological, Spencer, IN) with the Swiss LithoClast showed improved fragmentation times, reduced setup time, and decreased user fatigue with the StoneBreaker. No differences in stone-free rates or complications were noted. The LithoClast uses medical air and requires a pedal for activation, whereas the lighter-weight StoneBreaker uses a CO_2 cartridge, is triggered by hand, and produces 10 times the impact pressure. Because pneumatic lithotripsy is valuable in large and hard stone compositions, it has been combined with ultrasonic lithotripters to improve on the advantageous characteristics of both modalities (see following). The Clinical Research Office of the Endourological Society reviewed 5800 percutaneous nephrolithotomy procedures (from 96 centers) to assess success rates based on mean Hounsfield units and various surgical characteristics. On regression analysis, pneumatic lithotripsy showed the highest probability of stone-free status (90%) even when compared with combination ultrasonic/pneumatic modalities (82%) (Anastasiadis et al., 2013).

Key Points: Pneumatic Lithotripsy

- Pneumatic lithotripsy uses compressed air to drive a projectile forcefully against the probe tip, transmitting repetitive ballistic forces to the stone surface similar to a jackhammer.
- Causing limited mucosal erosions and transmural edema, pneumatic lithotrites cause the least amount of trauma compared with other intracorporeal lithotripters.
- The efficiency of stone fragmentation is improved by increasing probe diameter and pulse frequency independently.
- Stone migration is a significant disadvantage when treating ureteric stones with pneumatic lithotripsy.

Ultrasonic Lithotripsy

Ultrasonic lithotripsy affords a straightforward method of stone fragmentation, while simplifying extraction. **Instead of manually extracting fragments after treatment, a central channel for suction provides simultaneous stone debris aspiration during lithotripsy.** The most common applications currently are percutaneous nephrolithotomy and cystolithotripsy, although applications in ureteroscopy exist.

Basic Physics

Ultrasonic lithotrites pass electrical current through piezoceramic crystals, producing directional sound waves of 23,000 to 27,000 Hz. The hand piece houses the piezoelectric interface, and waves propagate as mechanical vibrational energy longitudinally down a solid or metal probe to where contact is made with the stone (Segura and LeRoy, 1984). **As the metal probe vibrates, when contact is made with the stone, this reverberation transmitted to the stone causes fracturing** (Teh et al., 1998) **along with the mechanical trauma of the oscillating metal tip against the surface** (LeRoy and Segura, 1984). Solid metal probes disintegrate stones by transmitting mechanical energy in a transverse plane, rather than longitudinally as with hollow probes. Local fracture can produce fine debris, which is aspirated by the probe; or if the probe is applied to fault lines, regional breakage can be created, leading to larger fragments.

Tissue Effects

Using an amplitude of 50 μm, no perforations could be created in rabbit bladders. Edema and submucosal hemorrhages were caused when only suction was applied, and irrigation (20 mL/min) kept frictional heating to a minimum. Metal splinters were observed embedding into the bladder wall, but after 9 weeks, minimal inflammation was noted on histology (Stackl and Marberger, 1985).

Piergiovanni et al. (1994) compared the Olympus ultrasonic lithotripter with EHL, pneumatic, and Ho:YAG laser lithotripters to assess tissue effects on a porcine bladder. **Ureteral and bladder perforations were impossible with**

perpendicular application of the ultrasonic and pneumatic probes. Histologic analysis immediately after application displayed denuded epithelial layers and edema.

When applied to immediately removed human renal pelvis samples (postnephrectomy), perpendicular application of suction alone caused 50% to 80% mucosal denudation, whereas the ultrasonic probe (21,000 Hz) caused 100% mucosal stripping with no evidence of muscularis injury, regardless of application time (Khemees et al., 2013a). A case report from 1988 described symptomatic hyponatremia during cystolithotripsy using an ultrasonic lithotrite and distilled water with a resulting intraperitoneal perforation. Although this treatment is not common today, it highlights that clinical conditions may not always reflect animal or in vitro models, and caution should still be exercised (Batra et al., 1988).

Ureteroscopy

The first clinical series reporting the use of ultrasonic lithotripsy comprised 412 patients treated for bladder stones in 1984. Probe diameters range from solid 2.5-Fr probes (for semirigid ureteroscopy) to 6.0-Fr used for cystoscopy and nephroscopy. Several bladder stone series corroborate the low complication rates and high success rates for stones of varying sizes using transurethral and suprapubic approaches (Cetin et al., 1988; El Khader et al., 1995; Razvi et al., 1996). A review of 176 patients **undergoing** bladder stone surgery during 1976 to 1994 noted an 88% success rate for ultrasonic lithotripsy, failing with “very hard stones” (Razvi et al., 1996).

Ureteroscopic fragmentation using ultrasonic probes was slower to gain popularity because of the required advancement in ureteroscopic technology and reduced probe sizes (2.5–4.5 Fr) required. With 2.5-Fr “solid wire” probes, a central lumen for aspiration is impossible. Some flexibility can be achieved for applications requiring active deflection during flexible ureteroscopy. Because EHL, pneumatic lithotripsy, and laser lithotripsy gained popularity around the same time as solid wire probes were developed, ureteroscopic applications of this technology never reached the same popularity as use of the technology in upper and lower tract indications (Gur et al., 2004). Preliminary reports documented flexible ultrasonic probes used through fiberoptic flexible scopes, resulting in an 87.5% success rate in 16 patients (Higashihara and Aso, 1989).

Pedro and Netto (2008) compared ESWL with ultrasonic lithotripsy in 235 consecutive patients with proximal ureteric stones with near-equal efficacy (85.6% ultrasonic lithotripsy vs. 90% ESWL success rates) and no differences in complication rates and mean procedure times. A review of all semirigid ureteroscopic ultrasonic series by Gur et al. (2004) identified 9 studies from 1983 to 1999 ranging from 7 to 311 patients. Pooled analyses of 863 patients identified an overall fragmentation rate of 89%, perforation rate of 2.5%, and “other complications” rate of 3.8% (including strictures, avulsions, sepsis, and false passage formation).

Percutaneous Surgery

Applications in percutaneous surgery closely followed cystolithotripsy, and by the mid 1980s, ultrasonic lithotripsy was being applied to percutaneous renal surgery (Segura and LeRoy, 1984). Used in pediatrics, horseshoe kidneys (Holman et al., 1986), and total staghorn calculi (Rodrigues Netto et al., 1988), ultrasonic lithotripsy has been a versatile tool in percutaneous surgery. In approaches ranging from anatrophic nephrolithotomy to percutaneous surgery, ultrasonic fragmentation was found to reduce operating times (from 210 minutes to 120 minutes), admission times (from 7 days to 5 days), and secondary interventions (from 50% to 20%), with a much earlier return to normal physical activity (43 days vs. 9 days) (Rodrigues Netto et al., 1988).

Newer combined technologies have improved on the fragmentation capabilities of ultrasonic lithotripsy by combining it with pneumatic lithotrites (see following). Dual-modality fragmentation with combined ultrasonic lithotripsy and pneumatic lithotripsy showed improved stone-free rates (92% vs. 85% ultrasonography alone), fewer secondary procedures, and decreased operative times without an increase in complication rates (Cho et al., 2010). With regard to harder stones, a prospective randomized trial assessing 30 patients with cystine, calcium oxalate monohydrate, or calcium phosphate stones showed a clear advantage for combined fragmentation, whereas softer stones had more favorable results with the ultrasonic lithotripter alone (Lehman et al., 2008).

Because contact must be made between the probe and stone, drilling or painting motions are used to trap the stone between urothelium and the probe. Smaller stones may be brought to the probe and held in place with suction alone. Continuous irrigation helps improve visualization, decrease heat buildup, and wash stone debris through the probe. When soft stones (e.g., struvite) are encountered, complete fragmentation and suction removal of the stone may be facilitated with ultrasonic lithotripsy. For harder stones, a drilling technique can be used to fracture the stone into manually extractable stones.

Larger pieces can be fragmented further or extracted manually. **Using continuous irrigation and suction keeps the probe tip cool while continuously removing particles** (Hofmann et al., 2002). As the fluid is evacuated through the hand piece, it cools the piezoceramic crystals, which can rapidly increase in temperature if proper suction is not maintained. Without adequate suction, in addition to a noticeably hot hand piece, visualization and stone clearance are impeded. It is important to tailor suctioning to the irrigation rate during probe activation; otherwise air can be introduced when aspiration outpaces irrigation inflow, obscuring the field with bubbles. This situation can be avoided by reducing the suction pressure, increasing irrigation height (or pressure), or intermittently clamping the suction tubing to allow enough fluid to remain in the renal pelvis/bladder for distention and visualization.

Key Points: Ultrasonic Lithotripsy

- Piezoceramic crystals produce directional sound waves of 23,000 to 27,000 Hz. Vibrational energy is transmitted from the probe tip to the stone surface, and fragment debris are aspirated through the central lumen of the tip.
- In vitro testing shows that direct contact with the urothelium causes mucosal stripping, although deeper perforations are difficult to achieve.
- Ultrasonic lithotripsy is useful in large soft stones; however, for harder stones, ultrasonic lithotripsy is most efficacious when paired with pneumatic lithotripsy in dual-modality lithotrites.

Holmium:YAG and Erbium:YAG Laser Lithotripsy

Holmium:YAG lasers have revolutionized kidney stone management and flexible ureteroscopy. In conjunction with improved optical systems in actively deflecting ureteroscopes, all areas of the genitourinary tract are now safely accessible for endoscopic lithotripsy using these lasers. Preliminary testing of the Er:YAG laser showed improved fragmentation efficiency of kidney stones compared with the Ho:YAG laser. Producing larger fragments with a smaller soft tissue penetration depth, this technology holds promise for future application in endourology.

Basic Physics

Laser physics for tissue-based applications are discussed in detail in Laser Instrumentation: Soft Tissue Applications.

Early on, questions surrounded the mechanism of lithotripsy of holmium lasers. Preceding technologies, such as the ruby and Nd:YAG lasers, used photoacoustic or photomechanical processes, in which light energy created shockwaves that fragmented stones. In contrast, photothermal stone breakage during holmium laser use was hypothesized based on early observations of “glowing hot stones.” Photothermal processes involve direct light energy absorption (“photo”) by stone surfaces causing rapid temperature (“thermal”) increases, before significant heat diffusion can occur.

Using a combination of techniques, Chan et al. (1999) **identified the predominant mode of Ho:YAG lithotripsy to be photothermal.** Mass loss experiments showed less fragmentation when stones −80°C were treated. As expected with a thermal mechanism, more energy was required to increase temperatures to ejection thresholds when starting below physiologic temperatures. After treatment, chemical analysis of all stone types showed thermal breakdown components. Finally, synchronized photography failed to identify fragmentation during bubble expansion or collapse, and measured pressures were too low (2 to 20 bar) to induce fracture.

Ablation crater volumes are associated with the irradiated surface photon density (fluence) and pulse energy. A “Moses effect” occurs by the rapid vaporization of fluid creating a vapor channel between the fiber tip and stone surface, allowing for more direct energy transfer. Although photoacoustic forces are not thought to contribute to fracture, interstitial water vaporization is likely involved with fragment ejection. Tensile and compressive forces, which dictate Nd:YAG lithotripsy, ESWL, and EHL, are not important (Chan et al., 1999).

Ho:YAG lasers produce fine fragments in large part because of photothermal energy absorption by urolithiasis; this results in the breakdown and disintegration of the heated area, causing craters and fragmentation (Qiu et al., 2010). As a result of the relatively long pulse rate (250 to 350 µsec), the Ho:YAG laser is considerably less efficient than other shorter pulse lasers. Because erbium (Er):YAG lasers have a shorter pulse duration and longer wavelength (2940 µm), they can still produce small fragments, but with improved efficiency over Ho:YAG lithotripsy.

The Er:YAG laser uses optical energy, and similar to Ho:YAG, irradiation of the stone's surface leads to increasing temperatures. Er:YAG lasers produce a 2940-nm wavelength, which has a fivefold increase in photothermal absorption by urolithiasis. Although shockwave production is insufficient for stone breakage in Ho:YAG lasers, Er:YAG lasers also show improved photoacoustic vapor bubble force transmission. With higher acoustic transients, the Er:YAG laser forms a torpedo-shaped vapor bubble in the interfacing fluid between probe and stone. The vapor bubble of the Ho:YAG laser is pear shaped, leading to increased energy loss laterally, producing weak shockwaves with minimal effect on stone fracture.

The radiant threshold for Er:YAG to initiate lithotripsy is 0.47 J/cm^2 at 2940 nm for calcium oxalate monohydrate compared with a Ho:YAG threshold of 7.36 J/cm^2. Deeper craters and larger ablation volumes are produced at this wavelength (Lee et al., 2006). **The combination of effective photothermal and photoacoustic lithotripsy of Er:YAG leads to faster fragmentation, with larger subsequent pieces.** In vitro studies showed larger fragments are created by Er:YAG; however, calcium oxalate monohydrate and cystine stone lithotripsy resulted in fragments less than 1 mm for both lasers, which clinically would be considered equivalent. Soft tissue depth of penetration is 0.79 µm, which is a significant improvement in safety compared with Ho:YAG (0.5 to 1 mm).

A problem with Er:YAG laser technology is that the hydroxy silica quartz fibers used in Ho:YAG machines are not compatible. Although sapphire fibers used with Er:YAG are too brittle and thick to be used in routine endourologic procedures, salivary stones were treated in wet-field applications using semirigid instrumentation (Raif et al., 2006). ZBLAN fluoride glass fibers have favorable properties in regard to reflection losses and light attenuation. However, because of a much lower melting point, durability is inadequate for clinical use. Before this technology can be applied to kidney stones, improved mechanical, thermal, and chemical fiber reliability is required. Hybrid fibers using fluoride cores with sapphire protection tips and circumferential cladding may help provide the transmission and flexibility required for endourology (Qiu et al., 2010).

Ureteroscopy

By reducing the diameter of ureteroscopes, slender intracorporeal lithotripters must pass easily through a working channel smaller than 4 Fr while allowing room for irrigation. These instruments also must be durable enough to be advanced and retracted repeatedly through a scope without breaking, even when deflected 270 degrees. Ho:YAG laser lithotripsy fulfills these requirements because hydroxy silica fibers are thin, flexible, and durable and possess transmission efficiencies, allowing for effective photothermal stone fragmentation.

Flexible ureteroscopy typically uses 200-µm laser fibers, which have a minimal impact on scope deflection. For semirigid ureteroscopy, 365-µm fibers are more suitable, although they can be used with flexible nephroscopy if minimal deflection is required (i.e., upper pole stones). Smaller semirigid ureteroscopes such as the 4.5-Fr needle (Richard Wolf, Vernan Hills, IL) have smaller working channels, and smaller laser fibers (<300 µm fibers) are preferred to allow for adequate irrigant flow. These are considered workhorse fibers because they have been shown to display maximal efficiency and durability while being typically cheaper (than 200-µm fibers) (Kuo et al., 1998).

Laser fiber tips should be advanced until clearly visualized by the operator (about one-fourth of the screen) (Talso et al., 2016). During flexible ureteroscopy, this may become problematic for lower pole stones because fiber advancement can damage the scope liner or optics or fracture the fiber itself. If a fractured fiber is used while in a scope, catastrophic damage and costly repairs can result. Fiber advancement should be performed with the scope tip in neutral position and then actively deflected to the area of interest. Newer fibers (i.e., Flexiva TracTip [Boston Scientific, Marlborough, MA]) have been created with a carved bulbous tip, theoretically allowing the fiber to pass through an already deflected scope without damage. The cladding helps permit high energy transfer even when bent, and using a 240-µm core, it is rated to handle settings up to 50 W. In an analysis of 96 clinically used fibers, none were broken. Bench testing revealed only a loss of 5 degrees of ureteroscopic active deflection (U-500 flexible ureteroscope [Stryker Endoscopy, San Jose, CA]; from 275 degrees to 270 degrees) (Khemees et al., 2013b). Alternatively, for stone repositioning from difficult-to-reach areas to the upper pole, using endoscopic baskets may help reduce the need for prolonged extreme deflection.

Ureteroscopic laser fragmentation can be performed by several techniques. Dust-sized fragments are produced by painting the fiber across the surface of a stone. Avoiding the creation of large fragments that are difficult to pass makes basket extraction unnecessary. With the use of lower energy levels of 0.2 J and higher pulse rates (i.e., 40 Hz), small debris and minimal retropulsion are encountered while trading off a reduction in total fragmentation. Controlling for total energy, increasing pulse energy levels were found to result in larger fragments with faster fragmentation times. Alternatively, as laser fragmentation becomes more time consuming as fragments become smaller, the surgeon can create large pieces and remove them using an endoscopic basket (Sea et al., 2012).

A technique dubbed “popcorning” uses the photoacoustic and the photothermal mechanisms of laser lithotripsy. **Photoacoustic and photothermal properties of a laser are functions of pulse duration and energy. Longer pulse duration produces greater photothermal functionality.** Although most Ho:YAG lasers have fixed durations of 250 to 350 µm, adjustable units are becoming more common. Shorter pulses yield higher peak power in resulting shockwaves. **Longer pulse duration reduces stone retropulsion and fiber tip degradation, with similar stone fragmentation rates compared with shorter pulse duration** (Bader et al., 2015; Kang et al., 2006; Wollin et al., 2017). In a ureteric model, increasing pulse duration from 300 to 700 µm reduced stone retropulsion by 50% (Finley et al., 2005). Pulse duration is inversely related to power and can manipulate stone motion depending on the circumstance; this can be helpful in difficult-to-reach anatomy (i.e., lower pole stones) or when numerous fragments exist in a confined area (i.e., minor calyx). The fiber tip is placed several millimeters away from the stones (and mucosa), and shockwaves produced by vapor bubbles collapsing cause stones to bounce like popcorn. As stones are agitated, intermittent contact with the laser fiber causes photothermal disintegration. As time passes, the “popcorning” effect continues to produce smaller and smaller fragments, resulting in a fine stone dust, which is passed without consequence. An in vitro experiment identified settings of 1.0 J and 20 Hz as giving the most efficient fragmentation when using this technique (Chawla et al., 2008).

With improving endoscopic technology, ureteroscopy and intracorporeal lithotripsy have replaced ESWL for treatment of many ureteric stones. A review of 82 patients undergoing either ESWL or ureteroscopy for impacted proximal stones showed no difference in 3-month stone-free rates (80% vs. 68%) or complications, although patients undergoing ESWL required more secondary procedures (Khalil, 2013). Similar results were achieved in a prospective randomized trial comparing 180 patients undergoing ESWL or semirigid ureteroscopy and laser lithotripsy for stones less than 2 cm. No significant differences were found between the two modalities in terms of 3-month stone-free rates, although retreatment rates were higher for ESWL (6.1% vs. 1.1%, $P < 0.001$) (Kumar et al., 2013). In contrast, a multicenter randomized trial of distal and midureteric stones (n = 156) treated with ESWL or ureteroscopy and laser lithotripsy showed an advantage for ureteroscopy. The 3-month stone-free rate was 91% for ureteroscopy (vs. 51% for ESWL), and retreatment rates were significantly lower (9% vs. 45% in ESWL) (Hendrikx et al., 1999). Several authors found cost savings associated with ureteroscopy and laser use compared with ESWL because of higher success rates and lower retreatment rates (Cone et al., 2014; Parker et al., 2004). Laser lithotripsy had lower initial ($7575 vs. $9507) and total ($9378 vs. $15,583) charges.

Comparing other intracorporeal lithotripsy modalities, a retrospective review of 394 patients with proximal ureteral stones treated with laser or pneumatic lithotripsy via semirigid ureteroscopy was performed, showing 86% were treated successfully with pneumatic lithotripsy; 14% required secondary ESWL for residual fragments (identified on radiograph). Laser lithotripsy produced a 97% stone-free rate, and only 2% required secondary procedures. Ureteral perforations were uncommon and not significantly different between groups (Bapat et al., 2007). In larger distal and mid-ureteric stones (mean diameter 13 mm), a prospective randomized trial showed a delayed stone-free rate of 95% with laser lithotripsy versus 85% with pneumatic lithotripsy on noncontrast computed tomography. Laser use was associated with less stone migration, although complication rates were for both arms (Kassem et al., 2012).

Stone position plays a large part in the success rates of ureteroscopy and laser lithotripsy. In a retrospective study, 272 patients undergoing flexible ureteroscopy from 2002 to 2006 and laser lithotripsy for renal stones were found to have an overall stone-free rate of 94% on follow-up noncontrast computed tomography. Stone-free rates were best for upper pole stones (100%), followed by middle pole stones (95%) and lower pole stones (90%), although not significantly different ($P = 0.338$). Similarly for the ureter, stone-free rates decreased from distal ureteral (96.8%) to proximal ureteral (79.4) stone location. Complication and retreatment rates were significantly higher with proximal stone location (Seitz et al., 2007).

Effective fragmentation using laser lithotripsy can be accomplished for any chemical stone composition, although efficiency is decreased with harder stones. Maintaining consistent power settings, magnesium ammonium phosphate stones are the most readily fractured, followed by calcium hydrogen phosphate dehydrate, cystine, uric acid, and calcium oxalate monohydrate. Increasing energy improves fragmentation for all stone types (Teichman et al., 1998). The differences are partly related to the melting points of the various stones as well as the vapor-surface interface. However, after reviewing ureteroscopic procedures performed on 86 renal and 101 ureteral stones, Wiener et al. (2012) failed to show any differences in operating room time related to stone composition. Perhaps because of active fragment removal using endoscopic baskets, coarse fragmentation techniques may not be as sensitive to chemical composition. Instead, if disintegrated to stone dust, presumably harder stones would require more time.

Because of its relatively high safety profile, laser lithotripsy has been applied to children (Fraser et al., 1999; Yeow et al., 2009), patients with bilateral stones (Atis et al., 2013; Huang et al., 2012), and patients with anatomic abnormalities (i.e., horseshoe kidney, duplicated systems, transplant grafts) (Hyams et al., 2012; Molimard et al., 2010). Ureteroscopy and laser use have been found to be safe in a retrospective review of 25 anticoagulated patients. Semirigid (6.9-Fr probe) and flexible (7.5-Fr probe) ureteroscopy was performed, and basket extraction was avoided by dusting all stones. Distal ureteral dilation (8/10-Fr coaxial dilator, balloon dilator, 14-Fr ureteric access sheath) was performed in 11 patients, and stents were placed in all patients after the procedure. Stone-free rates were 96% (100% distal ureter and mid-ureter, 89% proximal and intrarenal locations). For lower pole stones, upper pole repositioning was performed. No cases of significant bleeding or early termination secondary to bleeding were reported with laser use. Similar findings were reported in children with von Willebrand disease (Christman et al., 2012; eFig. 15.4).

Up-front and disposable costs for laser lithotripters may be an issue for some hospitals. Because of the versatility of the Ho:YAG laser, it can be used not only in all parts of the genitourinary tract but also for interventions not involving stones. Reusable laser fibers allow a significant cost savings; one study from two hospitals showed a savings of more than $64,000 by using 37 fibers (varying manufacturers and sizes) for 540 semirigid and flexible ureteroscopy cases (Knudsen et al., 2011).

Percutaneous Nephrolithotomy

Although laser lithotripsy is not the favored modality for use in large renal stone burdens treated percutaneously, it plays an important role in flexible instrumentation. Anterograde nephroscopy using flexible scopes can access calyces that rigid nephroscopes cannot reach, reducing the need for multiple accesses. For patients with large impacted ureteric stones, reimplanted ureters, and reconstructed bladders, antegrade flexible ureteroscopy and laser lithotripsy can allow straightforward access to the stone. Coarse fragmentation and basket extraction simplify the procedure because the ureteric portion proximal to the obstruction is often dilated, allowing for active retrieval of larger stones.

Laser fragmentation is central to percutaneous nephrolithotomy performed with reduced-diameter sheaths (i.e., minipercutaneous, ultra-minipercutaneous, micropercutaneous). Developed initially for pediatrics, the procedure is now used in adults with sheath diameters ranging from 24 Fr (8 mm) to 16 gauge (1.3 mm). With use of extremely narrow sheaths, techniques require special miniaturized imaging technologies and laser lithotripsy. Because stone extraction is impossible with extremely narrow sheaths, 200-µm core sized laser fibers are used to dust stones, and debris is cleared by pressurized irrigation or passive urine flow. Indications have yet to be clearly defined; however, studies comparing efficacy with flexible ureteroscopy, standard percutaneous nephrolithotomy, and ESWL have been performed. A randomized study comparing flexible ureteroscopy and micropercutaneous nephrolithotomy (16-gauge "all-seeing needle" and 272-µm laser fiber) was performed in 70 patients for stones less than 1.5 cm. Equivalent stone-free rates, complication rates, and length of stay were identified. Increased pain scores (1.9 vs. 1.6, $P = 0.046$), analgesic requirements, and hemoglobin loss (0.96 g/dL vs. 0.56 g/dL, $P < 0.001$) were observed in the minipercutaneous nephrolithotomy arm. All patients had ureteric access sheaths placed, although 40% fewer patients required stent placement in the minipercutaneous nephrolithotomy arm (20% vs. 60%) (Sabnis et al., 2013).

Bladder Stones

In 1978 Fair reported the benefits of using a ruby laser to produce "stress pulses," which were able to fracture stones of any color, shape, size, hardness, and composition (Fair, 1978). Since then, Ho:YAG has become a useful option in transurethral and percutaneous approaches. In larger stone burdens, laser may not be the first choice; however, many still prefer laser cystolithotripsy because of its safety and ease of use.

With larger stones, the degree of fragmentation and stone dust produced by laser lithotripsy can reduce efficiency and visualization and increase operating room time. Combining lithotripter modalities and approaches in patients with stones greater than 4 cm may help reduce operative time and improve visualization and stone clearance (Sofer et al., 2004). The combination of laser and ultrasonic lithotripsy allows for fragmentation of hard stones, while suctioning fragments and improving visualization. A combined percutaneous and transurethral approach can also improve flow and allow larger fragment removal and stone manipulation by two surgeons simultaneously without increasing complication rates (Sofer et al., 2004). Use of a 24-Fr scope through a 30-Fr Amplatz sheath (Cook Urological, Spencer, IN) placed through the urethra (with or without urethral dilation) has been reported to improve irrigation drainage, visualization, and stone localization during laser lithotripsy in female (Kawahara et al., 2012a; Ramanathan, 1999) and male (Okeke et al., 2004) patients.

Total stone burden (volume and area on noncontrast computed tomography) was the only variable found to correlate with total procedural time required for laser cystolithotripsy. Using 550-µm laser fibers (100-W laser, set between 1.5 and 3.5 J, 5 Hz), cystolithotripsy was performed through a 26-Fr resectoscope. Stone hardness (measured by Hounsfield units and chemical stone composition) did not appear to affect operating room time significantly. Male gender added procedural time, although lithotripsy time was not significantly different between sexes (Kawahara et al., 2012b).

An advantage of laser cystolithotripsy is its use in flexible cystoscopy, allowing for treatment in reconstructed bladders and challenging genitourinary anatomy that precludes use of rigid instruments. Flexible laser lithotripsy has been used under local anesthetic in healthy men with stones greater than 3 cm, with minimal pain and improvements in lower urinary tract symptoms, without significant complications (Kara et al., 2009).

In pediatric urolithiasis, instrument diameter plays a key role in management options. Bladder stones have been successfully treated using 8-Fr ureteroscopes with 550-µm laser fibers for stones less than 4 cm (Ramakrishnan et al., 2005). No laser-related complications were encountered perioperatively, and no children showed recurrences or urethral stricture formation in long-term follow-up (mean 48 months). In children with complicated genitourinary reconstructions, augmentations, and continence procedures, percutaneous laser cystolithotripsy through a previous suprapubic catheter site allowed for maximal stone fragmentation while minimizing the risk to intraperitoneal structures and/or vascular supply to bowel segments used for augmentation (Cain et al.,

2002).

When indicated, concomitant treatment of bladder stones and BPH has been reported using several modalities of prostatic resection, including green light laser (De la Torre et al., 2012), HoLEP (Shah et al., 2007), and TURP (Philippou et al., 2011), without significantly increasing the rate of complications. Bladder calculi are treated first to avoid injuring the resection bed after prostatic surgery or risk leaving stones behind should the procedure be terminated early. Rare cases of prostatic stones causing lower urinary tract symptoms and bladder outlet obstruction can also be treated with laser lithotripsy. Using a 550-µm laser fiber (1 to 1.5 J, 15 to 20 Hz) through a rigid cystoscope, Goyal et al. (2013) reported complete stone removal resulting in improved International Prostate Scoring System scores and improved peak flow rates at 3 months. Concurrent laser urethrotomy can be performed if necessary.

Key Points: Holmium:YAG Laser Lithotripsy

- Laser lithotripsy has brought versatility to intracorporeal lithotripsy by allowing safe fragmentation in virtually all areas of the genitourinary tract.
- Ho:YAG laser fragmentation is predominantly because of photothermal decomposition and possibly photoacoustic propulsion of fragments.
- Laser output can be adjusted based on rate (Hz), energy (J), pulse duration (µsec), and fiber size (µm).
- Maximal deflection is achieved with 200-µm core-sized fibers during flexible ureteroscopy; however, maximal efficiency is seen with 365-µm core-sized fibers.
- Proper laser fiber handling can help reduce scope damage and prolong the life of reusable fibers.
- Techniques used during stone fragmentation include painting and “popcorning,” which create fine stone dust (precluding removal), or crude fragmentation for basket extraction.
- Laser lithotripsy can produce the smallest fragments and is efficacious in all stone compositions.
- Smaller stone fragments can be obtained with lower pulse energies and higher frequencies (“dusting”), whereas larger fragments can be obtained with higher pulse energies and lower frequencies. Longer pulse duration

reduces stone retropulsion.

Dual-Modality Lithotripters

Newer modalities have been developed by combining ultrasonic and pneumatic lithotripters into a single hand piece. The Swiss LithoClast Ultra and CyberWand (Olympus, Southborough, MA) use different strategies to capitalize on the advantages of each modality. Pneumatic lithotripsy is effective at fragmenting harder stones, whereas ultrasonic action produces smaller fragments, while simultaneously removing them from the field. These hybrid systems are available only as rigid probes and can be used only in transurethral or percutaneous procedures (Fig. 15.5).

FIG. 15.5 Dual-modality lithotripter configurations.

LithoClast Ultra

The LithoClast Ultra was the first dual-modality lithotripter, combining two independently functioning hand pieces that are fixed together. **The front piece houses the ultrasonic lithotripter, with a central channel allowing**

throughway for the slender pneumatic probe. The 1-mm solid pneumatic probe sits within the suction channel of the 3.3-mm hollow ultrasonic probe. Fine-tuning of positioning of the pneumatic probe tip (relative to the ultrasonic tip) can be achieved using the depth wheel built into the hand piece. Pneumatic activity can be triggered as needed or continuously from 2 to 12 cycles per second. The ultrasonic probe can be adjusted based on power and duty cycle. A composite pedal allows selective or combined use of each modality. Three cords attach to the hand piece for medical air, ultrasonic power, and suction. In-line suction allows continuous fragment removal and collection (using a stone trap) and hand piece cooling.

For maximal control, the tip of the pneumatic probe should be slightly recessed from the outer ultrasonic probe. In this way, the ultrasonic probe can make maximal contact with the stone surface, and pneumatic retropulsion is limited. When activated, the pneumatic tip advances and strikes the stone beyond the ultrasonic probe tip. If large immobile stones are being treated (i.e., staghorn calculi), better fragmentation can be achieved by adjusting the pneumatic probe 2.5 mm past the ultrasonic sheath; however, simultaneous treatment of smaller fragments may become more challenging (VonDerHaar et al., 2010).

CyberWand

The CyberWand uses an ultrasonic hand piece producing vibrational energy by means of a piezoceramic crystal. Disposable probes are made of an inner 2.77-mm and outer 3.75-mm cylindric metal tube. The inner probe screws onto the handset, extending 1 mm past the tip of the outer sheath. The fixed inner probe vibrates at a frequency of 21,000 Hz. Because of a free mass washer and dampening spring, the free-floating outer probe vibrates at approximately 1000 Hz, oscillating longitudinally 1 mm. Selecting “large stone” on the foot pedal couples both sheaths. **Ultrasonic energy from the inner sheath is transmitted to the outer sheath, which moves in a ballistic manner, similar to pneumatic lithotripters** (Auge et al., 2002). The “small stone” pedal allows for finer control and activates only the ultrasonic action of the inner probe. The hollow lumen of the inner sheath of the probe incorporates irrigation suction, which simultaneously clears stone debris during fragmentation while cooling the hand piece.

Noise levels related to CyberWand fragmentation (93 dB) were determined to be the loudest (at ear level) compared with the Storz Ultrasonic lithotrite (Storz, El Segundo, CA; 77 dB), Olympus LUS-2 single modality ultrasonic lithotripter (Olympus, Southborough, MA; 68 dB), and Ho:YAG laser (60 dB). If used for more than 90 minutes per day, only the CyberWand is above the threshold set by the US Department of Labor and Occupational Health and Safety Administration for risk of noise-related occupational hearing loss (Soucy et al., 2008).

ShockPulse-SE

The ShockPulse-SE (Olympus, Center Valley, PA) is a dual-action, single-probe lithotripter using either ultrasonic alone or ultrasonic along with intermittent ballistic shockwave energy to achieve rapid stone fragmentation. A large-probe lumen allows for simultaneous aspiration of stone fragments. The ShockPulse-SE is the first on the market with surgeon-controlled hand activation and an integrated suction control hand piece for improved ergonomics, obviating the need for an additional foot pedal on the floor. Probes of varying sizes (0.97 mm–3.76 mm) are available for various applications, including standard percutaneous nephrolithotomy (PCNL), mini-PCNL, semirigid ureteroscopy, and treatment of bladder stones.

Tissue Effects

Using fresh human urothelium from nephrectomy specimens, perpendicular application of the CyberWand and LithoClast was done for 2 to 8 seconds. Tissue effects were compared with untreated areas and control specimens (suction-only probe contact). Suction alone showed 50% to 80% denudation of urothelium, with no changes identified in the subepithelial or muscular layer. The CyberWand “small stone” setting showed 100% urothelial denudation, with separation of the subepithelial connective tissue layer and no muscular damage. During use with the “large stone” setting, a greater amount of subepithelial edema and muscular rupture was noted with increasing contact time to the mucosa.

For ultrasonography-only settings, the Swiss LithoClast Ultra and CyberWand (“small stone” setting) showed 100% urothelial denudation, with separation of the subepithelial connective tissue layer and no muscular damage. With 2 seconds of exposure, minimal tissue damage was noted. **Increasing contact time led to increased mucosal denudation and submucosal vacuolation.**

Muscle rupture worsened with increasing exposure times except for the single modality "small stone" setting on the CyberWand, which was unable to cause muscle rupture. Based on these findings, the authors concluded that both modalities were safe, although contact time when using dual-modality settings should be minimized when possible (Khemees et al., 2013a).

Clinical Use

Several studies showed that the combination of pneumatic and ultrasonic lithotripters is more efficient compared with pneumatic or ultrasonic lithotripsy alone. Each modality separately cleared phantom stones 3.8 times (pneumatic) and 1.7 times (ultrasonic) slower than combination lithotripsy with the Swiss LithoClast Ultra (Soucy et al., 2008). An in vitro experiment using gypsum stones was performed to compare penetration times of the CyberWand and Swiss LithoClast Ultra. Penetration times were 41% shorter with the CyberWand with no significant differences in overheating, blockages, or malfunctioning (Kim et al., 2007).

Clinical use was assessed by randomly assigning 20 patients to either ultrasonic or combined modality lithotripsy during percutaneous nephrolithotomy. Combination lithotripsy reduced fragmentation time from 43.7 minutes to 21.1 minutes ($P = 0.036$), with slightly improved complication and stone-free rates (Pietrow et al., 2003). To compare the clinical efficacy between dual-modality lithotrites, 138 patients with staghorn calculi were randomly assigned to either CyberWand or Swiss LithoClast Master fragmentation. Although shorter operative times were encountered with CyberWand allocation (77.1 minutes vs. 84.3 minutes, $P = 0.049$), no differences in stone clearance or complication rates were noted (Li et al., 2013).

Surgical technique during treatment can affect efficiency of stone fracture. Applying force to a hand piece against a stone can improve or reduce fragmentation efficacy. The rate of stone mass removal was measured in an in vitro analysis using 400 g, 1000 g, and 2000 g of in-line force on a CyberWand and Swiss LithoClast Ultra hand piece. For the CyberWand dual-modality settings, 400 g and 1000 g were significantly more efficient than 2000 g, whereas with ultrasonography alone (on the Swiss LithoClast), efficiency increased with pressure and rotation of the probe by 90 degrees. This study also corroborates the improved fragmentation of the CyberWand against all settings of the Swiss LithoClast (Goldman et al., 2009). Too much pressure on the

CyberWand may impede the movement of the outer low-frequency probe, leaving fragmentation to occur only with the ultrasonic action of the inner probe. However, the LithoClast Ultra functions better at higher pressures and with rotation. Because the pneumatic and the ultrasonic components are actively driven by separate mechanisms, applying pressure does not prevent movement as in the CyberWand (Goldman et al., 2009).

Key Points: Dual-Modality Lithotripters

- Dual-modality lithotripters combine ultrasonic and pneumatic lithotripsy to take advantage of the benefits of each.
- Swiss LithoClast uses two independently driven lithotrites combined in one hand piece.
- The CyberWand uses a double-layered probe with a central ultrasonic probe and a passively coupled low-frequency outer probe, which provides ballistic stone fragmentation.
- The ShockPulse-SE uses a single probe with ultrasonic and intermittent ballistic shockwave energy to achieve rapid stone fragmentation along with a surgeon-controlled hand piece allowing for device activation and suction control.
- When friable tissues are present or visualization is suboptimal secondary to bleeding or challenging anatomy, single-modality lithotripsy should be used. Reducing lithotripsy to ultrasonic-only activity and minimizing urothelial contact time lessen the potential for mucosal complications (i.e., bleeding, perforation, future stricture formation).

Evaluation and Management of Hematuria

Stephen A. Boorjian MD, Jay D. Raman MD, FACS, Daniel A. Barocas MD, MPH, FACS

Hematuria has been recognized as a sign of medical illness since antiquity (Armstrong, 2006; Ellis, 1979; Shokeir and Hussein, 1999). Yet it is only in the modern era that we have developed the technology to detect microscopic blood, the means to identify the source of hematuria, and the understanding of anatomy, physiology, and disease processes underlying this important sign. Today, hematuria is one of the most common indications for urologic evaluation (Mariani et al., 1989) and is recognized as a sign of potentially important illness. Therefore knowledge of the differential diagnosis, principles of evaluation, and strategies for management of hematuria is critical.

Classification and Timing of Hematuria

Hematuria may be classified according to its visibility and timing during the urinary stream. That is, gross hematuria (GH), sometimes referred to as *frank hematuria*, *macrohematuria*, or *visible hematuria*, is hematuria that can be seen with the naked eye. GH may be further characterized as initial, terminal, or total, depending on the phase of the urinary stream in which it is visible. This characterization may give some indication of the source of hematuria, with initial hematuria most commonly emanating from a urethral source; terminal hematuria from the bladder trigone, bladder neck, or prostate; and total hematuria from the bladder or above (Sokolosky, 2001).

GH must be distinguished from pigmenturia, which may be due to endogenous sources (e.g., bilirubin, myoglobin, porphyrins), foods ingested (e.g., beets and rhubarb), drugs taken (e.g., phenazopyridine), and simple dehydration. This distinction can be made easily by urinalysis with microscopy. Notably, myoglobinuria and other factors can cause false-positive chemical tests (e.g., urine dipstick) for hemoglobin, so urine microscopy is required to confirm the diagnosis of hematuria. **GH also must be distinguished from vaginal bleeding in women,** which usually can be achieved by obtaining a careful menstrual history, collecting the specimen when the patient is not having menstrual or gynecologic bleeding, or, if necessary, obtaining a catheterized specimen. GH may also be detected by the presence of blood spotting on the undergarments of incontinent patients. After ruling out vaginal bleeding and mimics of hematuria, a urologic source must be suspected.

Microscopic Hematuria

In contrast to GH, microscopic hematuria, or microhematuria (MH), is a sign rather than a symptom; a laboratory diagnosis defined as the presence of red blood cells (RBCs) on microscopic examination of the urine not evident on visual inspection of the urine. **The prevalence of MH among healthy participants in screening studies is approximately 6.5% (95% confidence interval [CI] 3.4 to 12.2),** with higher rates noted in studies with a predominance of males, older patients, and smokers (Davis et al., 2012). MH may be categorized by the presence or absence of associated symptoms and may be quantified according to number of RBCs per high-power field (HPF). The proper collection of a urine specimen and the details of urine dipstick testing and urinalysis are covered in Chapter 1.

Criteria for the Diagnosis of Microhematuria

A small number of RBCs may pass into the urine even under normal conditions, and normal processes (e.g., sexual activity, exercise) can result in minor amounts of MH (Kohanpour et al., 2012). At the same time, it has been shown that **MH caused by significant medical conditions, such as urinary tract malignancy, can be intermittent** (Davis et al., 2012). In fact, a meta-analysis reported that the rate of malignancy detected among patients evaluated for a single positive urinalysis was 3.6% (Davis et al., 2012). As such, **the American Urological Association (AUA) guideline panel defined MH as three or more RBCs/HPF,** concluding that higher thresholds would lead to missed opportunities to diagnose treatable urologic conditions (Davis et al., 2012; Nielsen and Qaseem, 2016). Moreover, the AUA guideline panel determined that **a single positive urinalysis is sufficient to prompt evaluation** (Davis et al., 2012). Other national and organizational guidelines vary with respect to criteria for MH diagnosis (Linder et al., 2017; Schmitz-Dräger et al., 2016; Table 16.1). Such differences in thresholds for initiating an evaluation reflect efforts to balance the benefits, harms, and costs associated with MH evaluation. Importantly, none have been robustly validated.

			elevated leukocytosis		

CT, Computed tomography; *HPF,* high-power field; *IVP,* intravenous pyelogram; *RBC,* red blood cell; *RUS,* renal ultrasound; *UA,* urinalysis; *US,* ultrasound.

Requirement for Microscopic Evaluation

The results of urine dipstick tests must be confirmed on urinalysis with microscopy and alone are considered insufficient to prompt an evaluation according to most authorities (Davis et al., 2012; Jeffries et al., 2016; Nielsen and Qaseem, 2016). Indeed, chemical tests for hematuria detect the peroxidase activity of hemoglobin using benzidine, and therefore conditions such as myoglobinuria can falsely activate the test (Mariani et al., 1984). Thus a positive dipstick test merits microscopic examination of the urinary sediment but does not warrant full evaluation unless microscopy confirms the presence of three or more RBCs/HPF. If the urinalysis with microscopy is not confirmatory, but the clinician remains suspicious, repeat microscopic testing is reasonable with the frequency individualized based on provider judgment.

Specimens collected immediately after prolonged recumbency (first void in morning) or after vigorous physical or sexual activity may be falsely positive for hematuria (Addis, 1926; Kincaid-Smith, 1982). In addition, dilute urine (osmolality <308 mOsm) may result in false-negative microscopic examination as a result of RBC lysis (Vaughan and Wyker, 1971).

Causes of Microhematuria

In most studies, **one-third to two-thirds of patients evaluated for MH have been found to have a demonstrable cause** (Mohr et al., 1986; Murakami et al., 1990), including calculus (6.0%), benign prostatic enlargement (12.9%), urethral stricture (1.4%), and various other conditions (Table 16.2; Davis et al., 2012). Notably, **the evaluation of patients with MH has been found to yield a diagnosis of malignancy in 0.68% to 4.3% of cases,** depending on the characteristics of the population evaluated, the threshold for evaluation, and the completeness of the evaluation (Davis et al., 2012; Jung et al., 2011; Price et al., 2014). **The likelihood of identifying a malignancy has been found to be greater among patients with higher levels of microscopic hematuria (>25 RBCs/HPH), GH, or risk factors for malignancy** (Lippmann et al., 2017; Loo et al., 2013; Shephard et al., 2012; Sultana et al., 1996; Box 16.1).

TABLE 16.2

Differential Diagnosis of Asymptomatic Microhematuria[a]

CATEGORY	EXAMPLES	COMMON CLINICAL PRESENTATION AND RISK FACTORS
Neoplasm	Any	See Box 16.1
	Bladder cancer	Older age, male predominance, tobacco use, occupational exposures, irritative voiding symptoms
	Ureteral or renal pelvis cancer	Family history of early colon cancers or upper tract tumors, flank pain
	Renal cortical tumor	Family history of early kidney tumors, flank pain, flank mass
	Prostate cancer	Older age, family history, African-American
	Urethral cancer	Obstructive symptoms, pain, bloody discharge
Infection/inflammation	Any	History of infection
	Cystitis	Female predominance, dysuria
	Pyelonephritis	Fever, flank pain, diabetes, female predominance
	Urethritis	Exposure to sexually transmitted infections, urethral discharge, dysuria
	Tuberculosis	Travel to endemic areas
	Schistosomiasis	Travel to endemic areas
	Hemorrhagic cystitis	See Box 16.2
Calculus	Any	
	Nephroureterolithiasis	Flank pain, family history, prior stone
	Bladder stones	Bladder outlet obstruction
Benign prostatic enlargement		Male, older age, obstructive symptoms
Medical renal disease[b]	Any	Hypertension, azotemia, dysmorphic erythrocytes, cellular casts, proteinuria
	Nephritis	
	IgA nephropathy	
Congenital or acquired anatomic abnormality	Polycystic kidney disease	Family history of renal cystic disease

	Ureteropelvic junction obstruction Ureteral stricture Urethral diverticulum Fistula	History of UTI, stone, flank pain History of surgery or radiation, flank pain, hydronephrosis; stranguria, spraying urine Discharge, dribbling, dyspareunia, history of UTI, female predominance Pneumaturia, fecaluria, abdominal pain, recurrent UTI, history of diverticulitis or colon cancer
Other	Exercise-induced hematuria[c]	Recent vigorous exercise
	Endometriosis	Cyclic hematuria in a menstruating woman
	Hematologic or thrombotic disease	Family history or personal history of bleeding or thrombosis
	Papillary necrosis	African-American, sickle cell disease, diabetes, analgesic abuse
	Arteriovenous malformation	
	Renal vein thrombosis	
	Interstitial cystitis	Voiding symptoms
	Trauma	History
	Recent genitourinary surgery or instrumentation	History

[a] Differential diagnosis, having ruled out obvious benign causes, such as menstruation, recent instrumentation, uncomplicated cystitis, etc.

[b] Presence of hematologic illness, medical renal illness or use of anticoagulants or antiplatelet agents does not preclude the need for a hematuria evaluation.

[c] Exercise-induced hematuria is a diagnosis of exclusion. Absence of hematuria after abstinence from exercise must be confirmed.

IgA, Immunoglobulin A; *UTI,* urinary tract infection.

Box 16.1

Common Risk Factors for Urinary Tract Malignancy in Patients With Microscopic Hematuria

Male gender
Age older than 35 years
Past or current smoking history
Occupational or other exposure to chemicals or dyes (benzenes or aromatic amines)
Analgesic abuse
History of gross hematuria
History of urologic disorder or disease
History of irritative voiding symptoms
History of pelvic irradiation
History of chronic urinary tract infection
Exposure to known carcinogenic agents or chemotherapy such as alkylating agents
History of chronic indwelling foreign body

Modified from 2012 American Urological Association guidelines.

Selecting Patients for Evaluation of Microhematuria

The AUA guidelines recommend evaluating all adults with asymptomatic microscopic hematuria, with few exceptions, whereas other organizations have put forth narrower criteria for evaluation (Linder et al., 2017; Schmitz-Dräger et al., 2016; see Table 16.1). Specifically, the AUA and American College of Physicians High-Value Care Task Force recommend evaluating patients with MH “in the absence of an obvious benign cause” such as infection and menstruation (Davis et al., 2012; Nielsen and Qaseem, 2016). As such, **patients who are found to have MH in the setting of a suspected benign cause must have that benign cause substantiated by clinical evidence and be further evaluated once the suspected benign cause is resolved.** Unfortunately, uniform agreement does not exist on how to identify benign causes of hematuria. Perhaps as a result, substantial delays in diagnosis and inferior bladder cancer outcomes have occurred related to repeated empirical treatment of urinary tract infection (UTI) and voiding symptoms, particularly among women (Henning et al., 2013; Lyratzopoulos et al., 2013; Tracey et al., 2014). Thus it may be recommended that the **presence of infection be confirmed with a urine culture and the urinalysis should be repeated after treatment of the UTI to document**

resolution of the hematuria. If hematuria persists, further evaluation is warranted.

In addition, recent vigorous exercise may be associated with MH, but this entity should be considered a diagnosis of exclusion (Kincaid-Smith, 1982; Kohanpour et al., 2012; McInnis et al., 1998). Thus it is necessary to confirm the absence of MH after a period of abstinence from exercise. In addition, **patients who develop hematuria (microscopic or gross) who are taking anticoagulation or antiplatelet medications (e.g., warfarin, enoxaparin, heparin, aspirin, clopidogrel, nonsteroidal anti-inflammatory agents) should undergo a complete evaluation in the same manner as patients not taking such medications** because the prevalence of hematuria, as well as the likelihood of finding genitourinary cancers, among patients with hematuria on anticoagulation has been reported to be no different from patients not taking such medications (Culclasure et al., 1994; Davis et al., 2012; Jeong et al., 2013; Khadra et al., 2000; Nielsen and Qaseem, 2016). In fact, it has been noted that these medications may unmask genitourinary lesions at an earlier stage (Antolak and Mellinger, 1969; Kraus et al., 1984; Mariani, 1989; Schuster and Lewis, 1987). In one series, 82% of anticoagulated male patients evaluated for GH were found to have significant urologic lesions (Antolak and Mellinger, 1969), and 13.9% of such lesions in another series were found to be malignant (Schuster and Lewis, 1987). More recently, a population-based study in Ontario, Canada, showed that patients taking antithrombotic agents were more than twice as likely to be diagnosed with bladder cancer within 6 months after an episode of hematuria (Wallis et al., 2017). MH in the setting of trauma is detailed in Chapters 52 and 90.
